## Abstract

Long-range migrations and the resulting admixture between populations have been an important force shaping human genetic diversity. Most existing methods for detecting and reconstructing historical admixture events are based on allele frequency divergences or patterns of ancestry segments in chromosomes of admixed individuals. An emerging new approach harnesses the exponential decay of admixture-induced linkage disequilibrium (LD) as a function of genetic distance. Here, we comprehensively develop LD-based inference into a versatile tool for investigating admixture. We present a new weighted LD statistic that can be used to infer mixture proportions as well as dates with fewer constraints on reference populations than previous methods. We define an LD-based three-population test for admixture and identify scenarios in which it can detect admixture that previous formal tests cannot. We further show that we can discover phylogenetic relationships between populations by comparing weighted LD curves obained using a suite of references. Finally, we describe several improvements to the computation and fitting of weighted LD curves that greatly increase the robustness and speed of the computation. We implement all of these advances in a software package, *ALDER*, which we validate in simulations and apply to test for admixture among all populations from the Human Genome Diversity Project (HGDP), highlighting insights into the admixture history of Central African Pygmies, Sardinians, and Japanese.

## INTRODUCTION

Admixture between previously diverged populations has been a common feature of human evolution, from at least the early periods of modern *Homo sapiens* to the present day, and has left significant genetic traces in contemporary populations (LI *et al.* 2008; WALL *et al.* 2009; REICH *et al.* 2009; GREEN *et al.* 2010; GRAVEL *et al.* 2011; PUGACH *et al.* 2011; PATTERSON *et al.* 2012). Resulting patterns of variation can provide information about migrations, demographic histories, and natural selection, and can also be a valuable tool for association mapping of disease genes in admixed populations (PATTERSON *et al.* 2004).

Recently, a variety of methods have been developed to harness large-scale genotype data to infer admixture events in the history of sampled populations, as well as to estimate a range of gene flow parameters, including ages, proportions, and sources. Some of the most popular approaches, such as STRUCTURE (PRITCHARD *et al.* 2000) and principal component analysis (PCA) (PATTERSON *et al.* 2006), use clustering algorithms to identify admixed populations as intermediates in relation to surrogate ancestral populations. In a somewhat similar vein, local ancestry inference methods (TANG *et al.* 2006; SANKARARAMAN *et al.* 2008; PRICE *et al.* 2009; LAWSON *et al.* 2012) analyze chromosomes of admixed individuals seeking to recover continuous blocks inherited directly from each ancestral population. Because recombination breaks down ancestry tracts through successive generations, the time of admixture can be inferred from the tract length distribution (POOL and NIELSEN 2009; PUGACH *et al.* 2011; GRAVEL 2012), with the caveat that accurate local ancestry inference becomes difficult as tract lengths decrease and the reference populations diverge from the true admixing populations.

A third class of methods makes use of allele frequency differentiation among populations to deduce the presence of admixture and estimate parameters, either with likelihood-based models (CHIKHI *et al.* 2001; WANG 2003; SOUSA *et al.* 2009; WALL *et al.* 2009; LAVAL *et al.* 2010; GRAVEL *et al.* 2011) or with phylogenetic trees built by averaging moments of the site frequency spectrum over large sets of SNPs (REICH *et al.* 2009; GREEN *et al.* 2010; PATTERSON *et al.* 2012; PICKRELL and PRITCHARD 2012; LIPSON *et al.* 2012). For example, $f$-statistic-based three- and

four-population tests for admixture (REICH *et al.* 2009; GREEN *et al.* 2010; PATTERSON *et al.* 2012) are highly sensitive in the proper parameter regimes and when the set of sampled populations sufficiently represents the phylogeny. One disadvantage of drift-based statistics, however, is that because the rate of genetic drift depends on population size, these methods do not allow for inference of the time that has elapsed since admixture events.

Finally, a fourth approach recently proposed by MOORJANI *et al.* (2011) that we further develop in this article uses associations between pairs of loci to make inference about admixture. In general, linkage disequilibrium (LD) in a population can be generated by selection, genetic drift, or population structure, and it is eroded by recombination. Within a homogeneous population, steady-state neutral LD is maintained by the balance of drift and recombination, typically becoming negligible in humans at distances of more than a few hundred kilobases (REICH *et al.* 2001; THE INTERNATIONAL HAPMAP CONSORTIUM 2007). Even if a population is currently well-mixed, however, it can retain longer-range *admixture LD* (ALD) from admixture events in its history involving previously separated populations. ALD is caused by associations between nearby loci co-inherited on an intact chromosomal block from one of the ancestral mixing populations (CHAKRABORTY and WEISS 1988). Recombination breaks down these associations, leaving a signature of the time elapsed since admixture that can be probed by aggregating pairwise LD measurements through an appropriate weighting scheme; the resulting weighted LD curve (as a function of genetic distance) then exhibits an exponential decay with rate constant giving the age of admixture (MOORJANI *et al.* 2011; PATTERSON *et al.* 2012). This approach to admixture dating is similar in spirit to local ancestry-based admixture dating, but LD statistics have the advantage of a simple mathematical form that facilitates error analysis.

In this paper, we comprehensively develop LD-based admixture inference, extending the methodology to several novel applications that constitute a versatile tool for investigating admixture. We first propose a cleaner functional form of the underlying weighted LD statistic and provide a precise mathematical development of its properties. As an immediate result of this theory, we observe that our new weighted LD statistic can be used to infer mixture proportions as well as dates, extending

the results of PICKRELL *et al.* (2012). Moreover, such inference can still be performed (albeit with reduced power) when data are available from only the admixed population and one surrogate ancestral population, whereas all previous techniques require at least two such reference populations. As a second application, we present an LD-based three-population test for admixture with sensitivity complementary to the 3-population $f$-statistic test (REICH *et al.* 2009; PATTERSON *et al.* 2012) and characterize the scenarios in which each is advantageous. We further show that phylogenetic relationships between true mixing populations and present-day references can be inferred by comparing weighted LD curves using weights derived from a suite of reference populations. Finally, we describe several improvements to the computation and fitting of weighted LD curves: we show how to detect confounding LD from sources other than admixture, improving the robustness of our methods against such effects, and we present a novel fast Fourier transform-based algorithm for weighted LD computation that reduces typical run times from hours to seconds. We implement all of these advances in a software package, *ALDER* (Admixture-induced Linkage Disequilibrium for Evolutionary Relationships).

We demonstrate the performance of *ALDER* by using it to test for admixture among all HGDP populations (LI *et al.* 2008) and compare its results to those of the 3-population test, highlighting the sensitivity trade-offs of each approach. We further illustrate our methodology with case studies of Central African Pygmies, Sardinians, and Japanese, revealing new details that add to our understanding of admixture events in the history of each population.

## METHODS

**Properties of weighted admixture LD:** In this section we introduce a weighted LD statistic that uses the decay of LD to detect signals of admixture given SNP data from an admixed population and reference populations. This statistic is similar to, but has an important difference from, the weighted LD statistic used in *ROLLOFF* (MOORJANI *et al.* 2011; PATTERSON *et al.* 2012). The formulation of our statistic is particularly important in allowing us to use the amplitude of weighted LD to make inferences about history. We begin by deriving quantitative mathematical properties

of this statistic that can be used to infer admixture parameters.

*Basic model and notation:* We will primarily consider a point-admixture model in which a population $C'$ descends from a mixture of populations $A$ and $B$ to form $C$, $n$ generations ago, in proportions $\alpha + \beta = 1$, followed by random mating. As we will discuss later, we can assume for our purposes that the genetic drift between $C$ and $C'$ is negligible, and hence we will simply refer to population $C$ when there is no risk of ambiguity. We are interested in the properties of the LD in population $C$ induced by admixture. Consider two biallelic, neutrally evolving SNPs $x$ and $y$ and for each SNP call one allele '0' and the other '1'. Denote by $p_A(x)$, $p_B(x)$, $p_A(y)$, and $p_B(y)$ the frequencies of the '1' alleles at $x$ and $y$ in the mixing populations $A$ and $B$ (at the time of admixture), and let $\delta(x) := p_A(x) - p_B(x)$ and $\delta(y) := p_A(y) - p_B(y)$ be the allele frequency differences.

Let $d$ denote the genetic distance between $x$ and $y$ and assume that $x$ and $y$ were in linkage equilibrium in populations $A$ and $B$. Then the LD in population $C$ immediately after admixture is

$$D_0 = \alpha\beta\delta(x)\delta(y),$$

where $D$ is the standard haploid measure of linkage disequilibrium as the covariance of alleles at $x$ and $y$ (CHAKRABORTY and WEISS 1988). After $n$ generations of random mating, the LD decays to

$$D_n = e^{-nd}D_0 = e^{-nd}\alpha\beta\delta(x)\delta(y)$$

assuming infinite population size (CHAKRABORTY and WEISS 1988). For a finite population, the above formula holds in expectation with a small adjustment factor caused by post-admixture drift (OHTA and KIMURA 1971):

$$E[D_n] = e^{-nd}e^{-n/2N_e}\alpha\beta\delta(x)\delta(y),$$

where $N_e$ is the effective population size. In most applications the adjustment factor $e^{-n/2N_e}$ is negligible, so we will omit it in what follows (MOORJANI *et al.* 2012, Note S1).

In practice, our data consist of unphased diploid genotypes, so we expand our notation accordingly. Consider sampling a random individual from population $C$. We use a pair of $\{0, 1\}$ random variables $X_1$ and $X_2$ to refer to the two alleles at $x$ and define random variables $Y_1$ and $Y_2$ likewise. Our unphased SNP data represent observations of the $\{0, 1, 2\}$ random variables $X := X_1 + X_2$ and $Y := Y_1 + Y_2$.

Define $z(x, y)$ to be the covariance

$$z(x, y) := \text{cov}(X, Y) = \text{cov}(X_1 + X_2, Y_1 + Y_2), \tag{1}$$

which can be decomposed into a sum of four haplotype covariances:

$$z(x, y) = \text{cov}(X_1, Y_1) + \text{cov}(X_2, Y_2) + \text{cov}(X_1, Y_2) + \text{cov}(X_2, Y_1). \tag{2}$$

The first two terms measure $D$ for the separate chromosomes, while the third and fourth terms vanish, since they represent covariances between variables for different chromosomes, which are independent. Thus, the expected total diploid covariance is simply

$$E[z(x, y)] = 2e^{-nd}\alpha\beta\delta(x)\delta(y). \tag{3}$$

*Relating weighted LD to admixture parameters:* MOORJANI *et al.* (2011) first observed that pairwise LD measurements across a panel of SNPs can be combined to enable accurate inference of the age of admixture, $n$. The crux of their approach was to harness the fact that the ALD between two sites $x$ and $y$ scales as $e^{-nd}$ multiplied by the product of allele frequency differences $\delta(x)\delta(y)$ in the mixing populations. While the allele frequency differences $\delta(\cdot)$ are usually not directly computable, they can often be approximated. Thus, MOORJANI *et al.* (2011) formulated a statistic, *ROLLOFF*, that dates admixture by fitting an exponential decay $e^{-nd}$ to correlation coefficients between LD measurements and surrogates for $\delta(x)\delta(y)$. (Note that MOORJANI *et al.* (2011) define $z(x, y)$ as a sample correlation coefficient, analogous to the classical LD measure $r$, as opposed to the sample covariance (1) we use here; we find the latter more mathematically convenient.)

We build upon these previous results by deriving exact formulas for weighted sums of ALD under a variety of weighting schemes that serve as useful surrogates for $\delta(x)\delta(y)$ in practice. These

calculations will allow us to interpret the magnitude of weighted ALD to obtain additional leverage on admixture parameters. Additionally, the theoretical development will generally elucidate the behavior of weighted ALD and its applicability in various phylogenetic scenarios.

Following MOORJANI *et al.* (2011), we partition all pairs of SNPs $(x, y)$ into bins of roughly constant genetic distance:

$$\mathcal{S}(d) := \{(x, y) \mid |x - y| \approx d\}.$$

Given a choice of weights $w(\cdot)$, one per SNP, we define the weighted LD at distance $d$ as

$$a(d) := \frac{\sum_{\mathcal{S}(d)} z(x, y)w(x)w(y)}{|\mathcal{S}(d)|}.$$

Assume first that our weights are the true allele frequency differences in the mixing populations, i.e., $w(x) = \delta(x)$ for all $x$. Applying (3),

$$\begin{aligned} E[a(d)] &= E\left[\frac{\sum_{\mathcal{S}(d)} z(x, y)\delta(x)\delta(y)}{|\mathcal{S}(d)|}\right] \\ &= \frac{\sum_{\mathcal{S}(d)} 2\alpha\beta E[\delta(x)^2\delta(y)^2]e^{-nd}}{|\mathcal{S}(d)|} \\ &= 2\alpha\beta F_2(A, B)^2 e^{-nd}, \end{aligned} \tag{4}$$

where $F_2(A, B)$ is the expected squared allele frequency difference for a neutral allele, as defined in REICH *et al.* (2009) and PATTERSON *et al.* (2012). Thus, $a(d)$ has the form of an exponential decay as a function of $d$, with time constant $n$ giving the date of admixture.

In practice, we must compute an empirical estimator of $a(d)$ from a finite number of sampled genotypes. Say we have a set of $m$ diploid admixed samples from population $C$ indexed by $i = 1, \ldots, m$, and denote their genotypes at sites $x$ and $y$ by $x_i, y_i \in \{0, 1, 2\}$. Also assume we have some finite number of reference individuals from $A$ and $B$ with empirical mean allele frequences $\hat{p}_A(\cdot)$ and $\hat{p}_B(\cdot)$. Then our ***ALDER*** software computes

$$\hat{a}(d) := \frac{\sum_{\mathcal{S}(d)} \widehat{\text{cov}(X, Y)}(\hat{p}_A(x) - \hat{p}_B(x))(\hat{p}_A(y) - \hat{p}_B(y))}{|\mathcal{S}(d)|}, \tag{5}$$

where

$$\widehat{\text{cov}(X, Y)} = \frac{1}{m - 1}\sum_{i=1}^{m}(x_i - \overline{x})(y_i - \overline{y})$$

is the usual unbiased sample covariance, so $E[\hat{a}(d)] = a(d)$ (assuming no background LD, so the ALD in population $C$ is independent of the drift processes producing the weights).

The weighted sum $\sum_{\mathcal{S}(d)} z(x,y)w(x)w(y)$ is a natural quantity to use for detecting ALD decay and is common to our weighted LD statistic $\hat{a}(d)$ and previous formulations of *ROLLOFF*. Indeed, for SNP pairs $(x, y)$ at a fixed distance $d$, we can think of equation (3) as providing a simple linear regression model between LD measurements $z(x, y)$ and allele frequency divergence products $\delta(x)\delta(y)$. In practice, the linear relation is made noisy by random sampling, as noted above, but the regression coefficient $2\alpha\beta e^{-nd}$ can be inferred by combining measurements from many SNP pairs $(x, y)$; in fact, the weighted sum $\sum_{\mathcal{S}(d)} \hat{z}(x,y)\hat{\delta}(x)\hat{\delta}(y)$ in the numerator of formula (5) is precisely the numerator of the least-squares estimator of the regression coefficient, which is the formulation of *ROLLOFF* given in MOORJANI *et al.* (2012, Note S1). Note that measurements of $z(x, y)$ cannot be combined directly without a weighting scheme, as the sign of the LD can be either positive or negative; additionally, the weights tend to preserve signal from ALD while depleting contributions from other forms of LD.

Up to scaling, our *ALDER* formulation is roughly equivalent to the regression coefficient formulation of *ROLLOFF* (MOORJANI *et al.* 2012, Note S1). In contrast, the original *ROLLOFF* statistic (PATTERSON *et al.* 2012) computed a *correlation* coefficient between $z(x, y)$ and $w(x)w(y)$ over $\mathcal{S}(d)$. However, the normalization term $\sqrt{\sum_{\mathcal{S}(d)} z(x,y)^2}$ in the denominator of the correlation coefficient can exhibit an unwanted $d$-dependence that biases the inferred admixture date if the admixed population has undergone a strong bottleneck (MOORJANI *et al.* 2012, Note S1) or in the case of recent admixture and large sample sizes. Beyond correcting the date bias, the $\hat{a}(d)$ curve that *ALDER* computes has the advantage of a simple form for its amplitude in terms of meaningful quantities, providing us additional leverage on admixture parameters. Additionally, we will show that $\hat{a}(d)$ can be efficiently computed via a new fast Fourier transform-based algorithm.

*Using weights derived from diverged reference populations:* In the above development we set the weights $w(x)$ to equal allele frequency differences $\delta(x)$ between the true mixing populations $A$ and

$B$. In practice, in the absence of ancient DNA data, it is impossible to sample allele frequencies from the time of mixture (an event in the past); instead, we substitute reference populations $A'$ and $B'$ that are accessible, setting $w(x) = \delta'(x) := p_{A'}(x) - p_{B'}(x)$. In a given data set, the closest surrogates $A'$ and $B'$ may be somewhat diverged from $A$ and $B$, so it is important to understand the consequences for the weighted LD $a(d)$.

We show in Appendix 1 that with reference populations $A'$ and $B'$ in place of $A$ and $B$, equation (4) for the expected weighted LD curve changes only slightly, becoming

$$E[a(d)] = 2\alpha\beta F_2(A'', B'')^2 e^{-nd}, \tag{6}$$

where $A''$ and $B''$ are the branch points of $A'$ and $B'$ on the $A$–$B$ lineage (Figure S1). Notably, the curve still has the form of an exponential decay with time constant $n$, the age of admixture, albeit with its amplitude (and therefore signal-to-noise) attenuated according to how far $A''$ and $B''$ are from the true ancestral mixing populations. Drift along the $A'$–$A''$ and $B'$–$B''$ branches likewise decreases signal-to-noise but in the reverse manner: higher drift on these branches makes the weighted LD curve noisier but does not change its expected amplitude. As above, given a real data set containing finite samples, we compute an estimator $\hat{a}(d)$ analogous to formula (5) that has the same expectation as $a(d)$.

*Using the admixed population as one reference:* Weighted LD can also be computed with only a single reference population by using the admixed population as the other reference (PICKRELL *et al.* 2012, Supplement Sec. 4). Assuming first that we know the allele frequencies of the ancestral mixing population $A$ and the admixed population $C$, the formula for the expected curve becomes

$$E[a(d)] = 2\alpha\beta^3 F_2(A, B)^2 e^{-nd}. \tag{7}$$

Using $C$ itself as one reference population and $X'$ as the other reference (which could branch anywhere between $A$ and $B$), the formula for the amplitude is slightly more complicated, but the curve retains the $e^{-nd}$ decay (Figure S2):

$$E[a(d)] = 2\alpha\beta(\alpha F_2(A, X'') - \beta F_2(B, X''))^2 e^{-nd}. \tag{8}$$

Derivations of these formulas are given in Appendix 1.

A subtle but important technical issue that arises when computing weighted LD with a single reference is that the true weighted LD statistic,

$$a(d) = \text{cov}(X, Y)(\mu_x - p(x))(\mu_y - p(y)),$$

where

$$\mu_x = \alpha p_A(x) + \beta p_B(x) \quad \text{and} \quad \mu_y = \alpha p_A(y) + \beta p_B(y)$$

are the mean allele frequencies of the admixed population (ignoring drift) and $p(\cdot)$ denote allele frequencies of the reference population, cannot be estimated by the naïve formula

$$\widehat{\text{cov}(X, Y)}(\hat{\mu}_x - \hat{p}(x))(\hat{\mu}_y - \hat{p}(y)).$$

that would appear to be a natural analog of (5). The difficulty is that the covariance term and the weights both involve the allele frequencies $\mu_x$ and $\mu_y$; thus, while the standard estimators for each term are individually unbiased, their product is a biased estimate of the weighted LD.

PICKRELL *et al.* (2012) circumvents this problem by partitioning the admixed samples in two groups, designating one group for use as admixed representatives and the other as a reference population; this method eliminates bias but reduces statistical power. We instead compute a polyache statistic (File S1) that provides an unbiased estimator $\hat{a}(d)$ of the weighted LD with maximal power.

*Affine term in weighted LD curve from assortative mating:* Weighted LD curves computed on real populations often exhibit a nonzero horizontal asymptote contrary to the exact exponential decay formulas we have derived above. Such behavior can be caused by assortative mating in violation of our model. We show in Appendix 1 that if we instead model the admixed population as consisting of randomly mating subpopulations with heterogeneous amounts $\alpha$—now a random variable—of mixed ancestry, our equations for the curves take the form

$$E[a(d)] = Me^{-nd} + K \tag{9}$$

for constants $M$ and $K$. Conveniently, however, the sum $M + K/2$ satisfies the same equations that the coefficient of the exponential does in the homogeneous case: adjusting equation (6) for assortative mating gives

$$M + K/2 = 2\alpha\beta F_2(A'', B'')^2 \tag{10}$$

for two-reference weighted LD, and in the one-reference case, modifying equation (8) gives

$$M + K/2 = 2\alpha\beta(\alpha F_2(A, X'') - \beta F_2(B, X''))^2. \tag{11}$$

For brevity, from here on we will take the amplitude of an exponential-plus-affine curve to mean $M + K/2$.

**Admixture inference using weighted LD:** We now describe how the theory we have developed can be used to investigate admixture. We detail novel techniques that use weighted LD to infer admixture parameters, test for admixture, and learn about phylogeny.

*Inferring admixture dates and fractions using one or two reference populations:* As noted above, our *ALDER* formulation of weighted LD hones the original two-reference admixture dating technique of *ROLLOFF* (MOORJANI *et al.* 2011), correcting a possible bias (MOORJANI *et al.* 2012, Note S1), and the one-reference technique (PICKRELL *et al.* 2012), improving statistical power. PICKRELL *et al.* (2012) also observed that weighted LD can be used to estimate ancestral mixing fractions. We further develop this application now.

The main idea is to treat our expressions for the amplitude of the weighted LD curve as equations that can be solved for the ancestry fractions $\alpha$ and $\beta = 1 - \alpha$. First consider two-reference weighted LD. Given samples from an admixed population $C$ and reference populations $A'$ and $B'$, we compute the curve $\hat{a}(d)$ and fit it as an exponential decay plus affine term: $\hat{a}(d) \approx \hat{M}e^{-nd} + \hat{K}$. Let $\hat{a}_0 := M + K/2$ denote the amplitude of the curve. Then equation (10) gives us a quadratic equation that we can solve to obtain an estimate $\hat{\alpha}$ of the mixture fraction $\alpha$,

$$2\hat{\alpha}(1 - \hat{\alpha})F_2(A'', B'')^2 = \hat{a}_0,$$

assuming we can estimate $F_2(A'', B'')^2$. Typically the branch point populations $A''$ and $B''$ are unavailable, but their $F_2$ distance can be computed by means of an admixture tree (PATTERSON *et al.* 2012; PICKRELL and PRITCHARD 2012; LIPSON *et al.* 2012). A caveat of this approach is that $\alpha$ and $1 - \alpha$ produce the same amplitude and cannot be distinguished by this method alone; additionally, the inversion problem is ill-conditioned near $\alpha = 0.5$.

The situation is more complicated when using the admixed population as one reference. First, the amplitude relation from equation (11) gives a quartic equation in $\hat{\alpha}$:

$$2\hat{\alpha}(1-\hat{\alpha})[\hat{\alpha}F_2(A, X'') - (1-\hat{\alpha})F_2(B, X'')]^2 = \hat{a}_0.$$

Second, the $F_2$ distances involved are in general not possible to calculate from an admixture tree (PATTERSON *et al.* 2012; LIPSON *et al.* 2012). In the special case that one of the true mixing populations is available as a reference, however—i.e., $X' = A$—PICKRELL *et al.* (2012) demonstrated that mixture fractions can be estimated much more easily. From equation (7), the expected amplitude of the curve is $2\alpha\beta^3 F_2(A, B)^2$. On the other hand, assuming no drift in $C$ since the admixture, a quick calculation shows that

$$F_2(A, C) = \beta^2 F_2(A, B),$$

and $F_2(A, C)$ is estimable directly from the sample data. Combining these relations, we can obtain our estimate $\hat{\alpha}$ by solving the equation

$$2\hat{\alpha}/(1-\hat{\alpha}) = \hat{a}_0/F_2(A, C)^2. \tag{12}$$

In practice, the true mixing population $A$ is not available for sampling, but a closely-related population $A'$ may be. In this case, the value of $\hat{\alpha}$ given by equation (12) with $A'$ in place of $A$ is a lower bound on the true mixture fraction $\alpha$ (Appendix 1). This bounding technique is the most compelling of the above mixture fraction inference approaches, as prior methods cannot perform such inference with only one reference population. In contrast, when more references are available, admixture tree-fitting methods readily estimate mixture fractions (PATTERSON *et al.*

2012; PICKRELL and PRITCHARD 2012; LIPSON *et al.* 2012). In such cases we believe that these $f$-statistic-based methods are more robust than LD-based inference, which suffers from the degeneracy of solutions noted above; however, the weighted LD approach can provide confirmation based on a different genetic mechanism.

*Testing for admixture:* Thus far, we have taken it as given that the population $C$ of interest is admixed and developed methods for inferring admixture parameters by fitting weighted LD curves. Now we consider the question of whether weighted LD can be used to determine whether admixture occurred in the first place. We develop a weighted LD-based formal test for admixture that is broadly analogous to the drift-based 3-population test (REICH *et al.* 2009; PATTERSON *et al.* 2012) but sensitive in different scenarios.

A complication of interpreting weighted LD is that certain demographic events other than admixture can also produce positive weighted LD that decays with genetic distance, particularly in the one-reference case. Specifically, if population $C$ has experienced a recent bottleneck or an extended period of low population size, it may contain long-range LD. Furthermore, this LD typically has some correlation with allele frequencies in $C$; consequently, using $C$ as one reference in the weighting scheme produces a spurious weighted LD signal.

In the two-reference case, LD from reduced population size in $C$ is generally washed out by the weighting scheme assuming the reference populations $A'$ and $B'$ are not too genetically similar to $C$. The reason is that the weights $\delta(\cdot) = p_{A'}(\cdot) - p_{B'}(\cdot)$ arise from drift between $A'$ and $B'$ that is independent of demographic events producing LD in $C$ (beyond genetic distances that are so short that the populations share haplotypes descended without recombination from their common ancestral haplotype). Thus, observing a two-reference weighted LD decay curve is generally good evidence that population $C$ is admixed. There is still a caveat, however. If $C$ and one of the references, say $A'$, share a recent population bottleneck (Figure S3), then the bottleneck-induced LD in $C$ can be correlated to the allele frequencies of $A'$, resulting once again in spurious weighted LD: in fact, the one-reference case we discussed above is the limiting case $A' = C$ of this situation.

With these considerations in mind, we propose an LD-based three-population test for admixture that includes a series of pre-tests safeguarding against the pathological demographies that can produce a non-admixture weighted LD signal. We outline the test now; details are in Appendix 2. Given a population $C$ to test for admixture and references $A'$ and $B'$, the main test is whether the observed weighted LD $\hat{a}(d)$ using $A'$–$B'$ weights is positive and well-fit by an exponential decay curve. We estimate a jackknife-based $p$-value by leaving out each chromosome in turn and re-fitting the weighted LD as an exponential decay; the jackknife then gives us a standard error on the fitting parameters—namely, the amplitude and the decay constant—that we use to measure the significance of the observed curve.

The above procedure allows us to determine whether there is sufficient signal in the weighted LD curve to reject the null hypothesis (under which $\hat{a}(d)$ is random "colored" noise in the sense that it contains autocorrelation). However, in order to conclude that the curve is the result of admixture, we must rule out the possibility that it is being produced by demography unrelated to admixture. We therefore apply the following pre-test procedure. First, we determine the distance to which LD in $C$ is significantly correlated with LD in either $A'$ or $B'$; to minimize signal from shared demography, we subsequently ignore data from SNP pairs at distances smaller than this correlation threshold. Then, we compute one-reference weighted LD curves for population $C$ with $A'$–$C$ and $B'$–$C$ weights and check that the curves are well-fit as exponential decays. In the case that $C$ is actually admixed between populations related to $A'$ and $B'$, the one-reference $A'$–$C$ and $B'$–$C$ curves pick up the same $e^{-nd}$ admixture LD decay signal. If $C$ is not admixed but has experienced a shared bottleneck with $A'$ (producing false-positive admixture signals from the $A'$–$B'$ and $B'$–$C$ curves), however, the $A'$–$C$ weighting scheme is unlikely to produce a weighted LD curve, especially when fitting beyond the LD correlation threshold.

This test procedure is intended to be conservative, so that a population $C$ identified as admixed can strongly be assumed to be so, whereas if $C$ is not identified as admixed, we are less confident in claiming that $C$ has experienced no admixture whatsoever. In situations where distinguishing admixture from other demography is particularly difficult, the test will err on the side of caution; for

example, even if $C$ is admixed, the test may fail to identify $C$ as admixed if it has also experienced a bottleneck. Also, if a reference $A'$ shares some of the same admixture history as $C$ or is simply very closely related to $C$, the pre-test will typically identify long-range correlated LD and deem $A'$ an unsuitable reference to use for testing admixture.

*Learning about phylogeny:* Given a triple of populations $(C; A', B')$, our test can identify admixture in the test population $C$, but what does this imply about the relationship of populations $A'$ and $B'$ to $C$? As with the drift-based 3-population test, test results must be interpreted carefully: even if $C$ is admixed, this does not necessarily mean that the reference populations $A'$ and $B'$ are closely related to the true mixing populations. However, computing weighted LD curves with a suite of different references can elucidate the phylogeny of the populations involved: our amplitude formulas (10) and (11) provide information about the locations on the phylogeny at which the references diverge from the true mixing populations.

More precisely, in the notation of Figure S1, the amplitude of the two-reference weighted LD curve is $2\alpha\beta F_2(A'', B'')^2$, which is maximized when $A'' = A$ and $B'' = B$ and is minimized when $A'' = B''$. So, for example, we can fix $A'$ and compute curves for a variety of references $B'$; the larger the resulting amplitude, the closer the branch point $B''$ is to $B$. In the one-reference case, as the reference $X'$ is varied, the amplitude $2\alpha\beta(\alpha F_2(A, X'') - \beta F_2(B, X''))^2$ traces out a parabola that starts at $2\alpha\beta^3 F_2(A, B)^2$ when $X'' = A$, decreases to a minimum value of 0, and increases again to $2\alpha^3\beta F_2(A, B)^2$ when $X'' = B$ (Figure S2). Here, the procedure is more qualitative because the branches $F_2(A, X'')$ and $F_2(B, X'')$ are less directly useful and the mixture proportions $\alpha$ and $\beta$ may not be known.

**Implementation of *ALDER*:** We now describe some more technical details of the software package we implemented, *ALDER*.

*Fast Fourier transform algorithm for computing weighted LD:* We developed a novel algorithm that algebraically manipulates the weighted LD statistic into a form that can be computed using a

fast Fourier transform (FFT), dramatically speeding up the computation (File S2). The algebraic transformation is made possible by the simple form (5) of our weighted LD statistic along with a genetic distance discretization procedure that is similar in spirit to *ROLLOFF* (MOORJANI *et al.* 2011) but subtly different; instead of binning the contributions of SNP pairs $(x, y)$ by discretizing the genetic distance $|x - y| = d$, we discretize the genetic map positions $x$ and $y$ themselves (using a default resolution of 0.05 cM). For two-reference weighted LD, the resulting FFT-based algorithm that we implemented in *ALDER* has computational cost that is approximately linear in the data size; in practice, it ran three orders of magnitude faster than *ROLLOFF* on typical data sets we analyzed.

*Curve-fitting:* We fit discretized weighted LD curves $\hat{a}(d)$ as $\hat{M}e^{-nd} + \hat{K}$ from equation (9), using least-squares to find best-fit parameters. This procedure is similar to *ROLLOFF*, but *ALDER* makes two important technical advances that significantly improve the robustness of the fitting. First, *ALDER* directly estimates the affine term $K$ that arises from assortative mating by using inter-chromosome SNP pairs that are effectively at infinite genetic distance (Appendix 1). The algorithmic advances we implement in *ALDER* enable efficient computation of the average weighted LD over all pairs of SNPs on different chromosomes, giving $\hat{K}$ and, importantly, eliminating one parameter from the exponential fitting. In practice, we have observed that *ROLLOFF* fits are sometimes sensitive to the maximum inter-SNP distance $d$ to which the weighted LD curve is computed and fit; *ALDER* eliminates this sensitivity.

Second, because background LD is present in real populations at short genetic distances and confounds the ALD signal (interfering with parameter estimates or producing spurious signal entirely), it is important to fit weighted LD curves starting only at a distance beyond which background LD is negligible. *ROLLOFF* used a fixed threshold of $d > 0.5$ cM, but some populations have longer-range background LD (e.g., from bottlenecks), and moreover, if a reference population is closely related to the test population, it can produce a spurious weighted LD signal due to recent shared demography. *ALDER* therefore estimates the extent to which the test population shares

correlated LD with the reference(s) and only fits the weighted LD curve beyond this minimum distance as in our test for admixture (Appendix 2).

We estimate standard errors on parameter estimates by performing a jackknife over the autosomes used in the analysis, leaving out each in turn. Note that the weighted LD measurements from individual pairs of SNPs that go into the computed curve $\hat{a}(d)$ are not independent of each other; however, the contributions of different chromosomes can reasonably be assumed to be independent.

**Data sets:** We primarily applied our weighted LD techniques to a data set of 940 individuals in 53 populations from the CEPH-Human Genome Diversity Cell Line Panel (HGDP) (ROSENBERG *et al.* 2002) genotyped on an Illumina 650K SNP array (LI *et al.* 2008). To study the effect of SNP ascertainment, we also analyzed the same HGDP populations genotyped on the Affymetrix Human Origins Array (PATTERSON *et al.* 2012). For some analyses we also included HapMap Phase 3 data (THE INTERNATIONAL HAPMAP CONSORTIUM 2010) merged either with the Illumina HGDP data set, leaving approximately 600K SNPs, or with the Indian data set of REICH *et al.* (2009) including 16 Andaman Islanders (9 Onge and 7 Great Andamanese), leaving 500K SNPs.

We also constructed simulated admixed chromosomes from 112 CEU and 113 YRI phased HapMap individuals using the following procedure, described in MOORJANI *et al.* (2011). Given desired ancestry proportions $\alpha$ and $\beta$, the age $n$ of the point admixture, and the number $m$ of admixed individuals to simulate, we built each admixed chromosome as a composite of chromosomal segments from the source populations, choosing breakpoints via a Poisson process with rate constant $n$, and sampling blocks at random according to the specified mixture fractions. We stipulated that no individual haplotype could be reused at a given locus among the $m$ simulated individuals, preventing unnaturally long identical-by-descent segments but effectively eliminating post-admixture genetic drift. For the short time scales we study (admixture occurring 200 or fewer generations ago), this approximation has little impact. We used this method in order to maintain some of the complications inherent in real data.

**Simulations:** First, we demonstrate the accuracy of several forms of inference from *ALDER* on simulated data. We generated simulated genomes for mixture fractions of 75% YRI / 25% CEU and 90% YRI / 10% CEU and admixture dates of 10, 20, 50, 100, and 200 generations ago. For each mixture scenario we simulated 40 admixed individuals according to the procedure above.

We first investigated the admixture dates estimated by *ALDER* using a variety of reference populations drawn from the HGDP with varying levels of divergence from the true mixing populations. On the African side, we used HGDP Yoruba (essentially identical to HapMap YRI) and San; on the European side, we used French (very close to CEU), Han, and Papuan. We computed two-reference weighted LD curves using pairs of references, one from each group, as well as one-reference curves using the simulated population as one reference and each of the above HGDP populations as the other.

For the 75% YRI mixture, estimated dates are nearly all accurate to within 10% (Table S1). The noise levels of the fitted dates (estimated by *ALDER* using the jackknife) are the lowest for the Yoruba–French curve, as expected, followed by the one-reference curve with French, consistent with the admixed population being mostly Yoruba. The situation is similar but noisier for the 90% YRI mixture (Table S2); in this case, the one-reference signal is quite weak with Yoruba and undetectable with San as the reference, due to the scaling of the amplitude (equation (11)) with the cube of the CEU mixture fraction.

We also compared fitted amplitudes of the weighted LD curves for the same scenarios to those predicted by formulas (10) and (11); the accuracy trends are similar (Tables S3, S4). Finally, we tested formula (12) for bounding mixture proportions using one-reference weighted LD amplitudes. We computed lower bounds on the European ancestry fraction using French, Russian, Sardinian, and Kalash as successively more diverged references. As expected, the bounds are tight for the French reference and grow successively weaker (Tables S5, S6). We also tried lower-bounding the African ancestry using one-reference curves with an African reference. In general, we expect lower bounds computed for the major ancestry proportion to be much weaker (Appendix 1), and

indeed we find this to be the case, with the only slightly diverged Mandenka population producing extremely weak bounds. An added complication is that the Mandenka are an admixed population with a small amount of West Eurasian ancestry (PRICE *et al.* 2009), which is not accounted for in the amplitude formulas we use here.

Another notable feature of *ALDER* is that, to a much greater extent than $f$-statistic methods, its inference quality improves with more samples from the admixed test population. As a demonstration of this, we simulated a larger set of 100 admixed individuals as above, for both 75% YRI / 25% CEU and 90% YRI / 10% CEU scenarios, and compared the date estimates obtained on subsets of 5–100 of these individuals with two different reference pairs (Tables S7, S8). With larger sample sizes, the estimates become almost uniformly more accurate, with smaller standard errors. By contrast, we observed in the course of running experiments that increasing the sample sizes for reference populations has only minimal effects on the performance of *ALDER* (data not shown). This is similar to the phenomenon that the precision of $f$-statistics does not improve appreciably with more than a moderate number of samples and is due to the inherent variability in genetic drift among different loci.

**Robustness:** A challenge of weighted LD analysis is that owing to various kinds of model violation, the parameters of the exponential fit of an observed curve $\hat{a}(d)$ may depend on the starting distance $d_0$ from which the curve is fit. We therefore explored the robustness of the fitting parameters to the choice of $d_0$ in a few scenarios (Figure 1). First, in a simulated 75% / 25% YRI–CEU admixture 50 generations ago, we find that the decay constant and amplitude are both highly robust to varying $d_0$ from 0.5 to 2.0 cM (Figure 1, top). This result is not surprising because our simulated example represents a true point admixture with minimal background LD in the admixed population.

In practice, we expect some dependence on $d_0$ due to background LD or longer-term admixture (either continuously over a stretch of time or in multiple waves). Both of these will tend to increase the weighted LD for smaller values of $d$ relative to an exact exponential curve, so that estimates of

the decay constant and amplitude will decrease as we increase the fitting start point $d_0$; the extent to which this effect occurs will depend on the extent of the model violation. We studied the $d_0$-dependence for two example admixed populations, HGDP Uygur and HapMap Maasai (MKK). For Uygur, the estimated decay constants and amplitudes are fairly robust to the start point of the fitting, varying roughly by $\pm 10\%$ (Figure 1, middle). In contrast, the estimates for Maasai vary dramatically, decreasing by more than a factor of 2 as $d_0$ is increased from 0.5 to 2.0 cM (Figure 1, bottom). This behavior is likely due to multiple-wave admixture in the genetic history of the Maasai; indeed, it is visually evident that the weighted LD curve for Maasai deviates from an exponential fit (Figure 1) and is in fact better-fit as a sum of exponentials.

It is also important to consider the possibility of SNP ascertainment bias, as in any study based on allele frequencies. We believe that for weighted LD, ascertainment could have modest effects on the amplitude, which depends on $F_2$ distances (PATTERSON *et al.* 2012; LIPSON *et al.* 2012), but will not affect the estimated date. Running *ALDER* on a suite of admixed populations in the HGDP under a variety of ascertainment schemes suggests that admixture date estimates are indeed quite stable to ascertainment (Table S9).

**Admixture test results on HGDP populations:** To compare the sensitivity of our LD-based test for admixture to the 3-population test, we ran both *ALDER* and the 3-population test on all triples of populations in the HGDP. Interestingly, while the tests concur on the majority of the populations they identify as admixed, each also identifies several populations as admixed that the other does not (Table 1), showing that the tests have differing sensitivity to different admixture scenarios.

*Admixture identified by only* ALDER*:* The 3-population test loses sensitivity primarily as a result of drift since splitting from the references' lineages. More precisely, using the notation of Figure S1, the 3-population test statistic $f_3(C; A', B')$ estimates the sum of two directly competing terms: $-2\alpha\beta F_2(A, B)$, the negative quantity arising from admixture that we wish to detect, and $F_2(A'', A) + F_2(B'', B) + 2F_2(C, C')$, a positive quantity from the "off-tree" drift branches. If the

latter term dominates, the 3-population test will fail to detect admixture regardless of the statistical power available. For example, Melanesians are only found to be admixed according to the *ALDER* test; the inability of the 3-population test to identify them as admixed is almost certainly due to the long off-tree drift from the Papuan branch prior to admixture. The situation is similar for the Pygmies.

Small mixture fractions also diminish the size of the admixture term $-2\alpha\beta F_2(A, B)$ relative to the off-tree drift, and we believe this effect along with post-admixture drift may be the reason Sardinians are detected as admixed only by *ALDER*. In the case of the San, who have a small amount of Bantu admixture (PICKRELL *et al.* 2012) the small mixture fraction may again play a role along with the lack of a reference population closely related to the pre-admixture San, meaning that using existing populations incurs long off-tree drift.

*Admixture identified by only the 3-population test:* There are also multiple reasons why the 3-population test can identify admixture that *ALDER* does not. For the HGDP European populations in this category (Table 1), the 3-population test is picking up a signal of admixture identified by PATTERSON *et al.* (2012) and interpreted there as a large-scale admixture event in Europe involving Neolithic farmers closely related to present-day Sardinians and an ancient northern Eurasian population. This mixture likely began quite anciently (e.g. 7,000-9,000 years ago when agriculture arrived Europe (BRAMANTI *et al.* 2009; SOARES *et al.* 2010; PINHASI *et al.* 2012)), and because admixture LD breaks down as $e^{-nd}$, where $n$ is the age of admixture, there is nearly no LD left for *ALDER* to harness beyond the correlation threshold $d_0$. An additional factor that may inhibit LD-based testing is that in order to prevent false-positive identifications of admixture, *ALDER* typically eliminates reference populations that share LD (and in particular, admixture history) with the test population, whereas the 3-population test can use such references.

To summarize, the *ALDER* and 3-population tests both analyze a test population for admixture using two references, but they detect signal based on different "genetic clocks." The 3-population test uses signal from genetic drift, which can detect quite old admixture but must overcome a

counteracting contribution from post-admixture and off-tree drift. The LD-based test uses recombination, which is relatively unaffected by small population size-induced long drift and has no directly competing effect, but has limited power to detect chronologically old admixtures because of the rapid decay of the LD curve. Additionally, as discussed above in the context of simulation results, the LD-based test may be better suited for large data sets, since its power is enhanced more by the availability of many samples. The tests are thus complementary and both valuable.

**Case studies:** We now present detailed results for several human populations, all of which *ALDER* identifies as admixed but are not found by the 3-population test (Table 1). We infer dates of admixture and in some cases additional historical insights.

*Pygmies:* Both Central African Pygmy populations in the HGDP, the Mbuti and Biaka, show evidence of admixture (Table 1), about $28 \pm 4$ generations (800 years) ago for Mbuti and $38 \pm 4$ generations (1100 years) ago for Biaka, estimated using San and Yoruba as reference populations (Figure 2A,C). The intra-population heterogeneity is low, as demonstrated by the negligible affine terms. In each case, we also generated weighted LD curves with the Pygmy population itself as one reference and a variety of second references. We found that using populations French, Han, or Yoruba as the second reference gave very similar amplitudes, but the amplitude was significantly smaller with the other Pygmy population or San as the second reference (Figure 2B,D). Using the amplitudes with Yoruba, we estimated mixture fractions of at least $15.9 \pm 0.9\%$ and $28.8 \pm 1.4\%$ Yoruba-related ancestry for Mbuti and Biaka, respectively.

The phylogenetic interpretation of the relative amplitudes is complicated by the fact that the Pygmy populations, used as references, are themselves admixed, but a plausible coherent explanation is as follows (see Figure 2E). We surmise that a proportion $\beta$ (lower bounds given above) of Bantu-related gene flow reached the native Pygmy populations on the order of 1000 years ago. The common ancestors of Yoruba and non-Africans with the Bantu population are genetically not very different from Bantu, due to high historical population sizes (branching at positions $X_1$ and

$X_2$ in Figure 2E). Thus, the weighted LD amplitudes using Yoruba or non-Africans as second references are nearly $2\alpha^3\beta F_2(A,B)^2$, where $B$ denotes the admixing Bantu population. Meanwhile, San and Western (resp. Eastern) Pygmies split from the Bantu-Mbuti (resp. Biaka) branch toward the middle or the opposite side from Bantu ($X_3$ and $X_4$), giving a smaller amplitude (Figure S2).

Our results are in agreement with previous studies that have found evidence of gene flow from agriculturalists to Pygmies (QUINTANA-MURCI *et al.* 2008; VERDU *et al.* 2009; PATIN *et al.* 2009; JARVIS *et al.* 2012). QUINTANA-MURCI *et al.* (2008) suggested based on mtDNA evidence in Mbuti that gene flow ceased several thousand years ago, but more recently, JARVIS *et al.* (2012) found evidence of admixture in Western Pygmies, with a local-ancestry-inferred block length distribution of $3.1 \pm 4.6$ Mb (mean and standard deviation), consistent with our estimated dates.

*Sardinians:* We detect a very small proportion of Sub-Saharan African ancestry in Sardinians, which our *ALDER* tests identified as admixed (Table 1; Figure 3A). To investigate further, we computed weighted LD curves with Sardinian as a test population and all pairs of the HapMap CEU, YRI and CHB populations as references (Table 2). We observed an abnormally large amount of shared long-range LD in chromosome 8, likely do to an extended inversion segregating in Europeans (PRICE *et al.* 2008), so we omitted it from these analyses. The CEU–YRI curve has the largest amplitude, suggesting both that the LD present is due to admixture and that the small non-European ancestry component, for which we estimated a lower bound of $0.6\pm0.2\%$, is from Africa. The existence of a weighted LD decay curve with CHB and YRI as references provides further evidence that the LD is not simply due to a population bottleneck or other non-admixture sources, as does the fact that our estimated dates from all three reference pairs are roughly consistent at about 40 generations (1200 years). Our findings thus confirm the signal of African ancestry in Sardinians reported in MOORJANI *et al.* (2011). The date, small mixture proportion, and geography are consistent with a small influx of migrants from North Africa, who themselves traced only a fraction of their ancestry ultimately to Sub-Saharan Africa, consistent with the findings of DUPANLOUP *et al.* (2004).

*Japanese:* Genetic studies have suggested that present-day Japanese are descended from admixture between two waves of settlers, responsible for the Jomon and Yayoi cultures (HAMMER and HORAI 1995; HAMMER *et al.* 2006; RASTEIRO and CHIKHI 2009). We also observed evidence of admixture in Japanese (Table 1), and while our ability to learn about the history is limited by the absence of a close surrogate for the original Paleolithic mixing population, we were able to take advantage of the one-reference inference capabilities of *ALDER*. We observed a clear weighted LD curve using HapMap JPT as the test population and JPT–CHB weights (Figure 3B). This curve yields an estimate of $45 \pm 6$ generations, or about 1,300 years, as the age of admixture. To our knowledge, this is the first time genome-wide data have been used to date admixture in Japanese. As with previous estimates based on coalescence of Y-chromosome haplotypes (HAMMER *et al.* 2006), our date is consistent with the archaeologically attested arrival of the Yayoi in Japan roughly 2300 years ago (we suspect that our estimate is from later than the initial arrival because admixture may not have happened immediately). Based on the amplitude of the curve, we also obtain a (likely very conservative) genome-wide lower bound of $41 \pm 3\%$ "Yayoi" ancestry using formula (12) (under the reasonable assumption that Han Chinese are fairly similar to the Yayoi population). It is important to note that observation of a single-reference weighted LD curve is not sufficient evidence to prove that a population is admixed, but we did find a pair of references with which the *ALDER* test identified Japanese as admixed, which, combined with previous work and the lack of any signal of reduced population size, makes us confident that our inferences are based on true historical admixture.

*Onge:* Lastly, we provide a cautionary example of weighted LD decay curves arising from demography and not admixture. We observed distinct weighted LD curves when analyzing the Onge, an indigenous population of the Andaman Islands. However, this curve is only present when using Onge themselves as one reference; moreover, the amplitude is independent of whether CEU, CHB, YRI, GIH (HapMap Gujarati), or Great Andamanese is used as the second reference (Figure 4), as expected if the weighted LD is due to correlation between LD and allele frequencies in the test

population alone (and independent of the reference allele frequencies). Correspondingly, *ALDER*'s LD-based test does not identify Onge as admixed using any pair of these references. Thus, while we cannot definitively rule out admixture, the evidence points toward internal demography (low population size) as the cause of the elevated LD, consistent with the current census of fewer than 100 Onge individuals.

## DISCUSSION

**Strengths of weighted LD for admixture inference:** The statistics underlying weighted LD are quite simple, making the formula for the expectation of $\hat{a}(d)$, as well as the noise and other errors from our inference procedure, relatively easy to understand. By contrast, local ancestry-based admixture dating methods (e.g., POOL and NIELSEN (2009) and GRAVEL (2012)) are sensitive to imperfect ancestry inference, and it is difficult to trace the error propagation to understand the ultimate effect on inferred admixture parameters. Similarly, the wavelet method of PUGACH *et al.* (2011) uses reference populations to perform (fuzzy) ancestry assignment in windows, for which error analysis is challenging.

Another strength of our weighted LD methodology is that it has relatively low requirements on the quality and quantity of reference populations. Our theory tells us exactly how the statistic behaves for any reference populations, no matter how diverged they are from the true ancestral mixing populations. In contrast, the accuracy of results from clustering and local ancestry methods is dependent on the quality of the reference populations used in ways that are difficult to characterize. On the quantity side, previous approaches to admixture inference require a surrogate for each ancestral population, whereas as long as one is confident that the signal is truly from admixture, weighted LD can be used with only one available reference to infer times of admixture (as in our analysis of the Japanese) and bound mixing fractions (as in our Pygmy case study and PICKRELL *et al.* (2012)), problems that were previously intractable.

Weighted LD also advances our ability to test for admixture. As discussed above, *ALDER* offers complementary sensitivity to the 3-population test and allows the identification of additional

populations as admixed. Another formal test for admixture is the 4-population test (REICH *et al.* 2009; PATTERSON *et al.* 2012), which is quite sensitive but also has trade-offs; for example, it requires three distinctly branching references, whereas *ALDER* and the 3-population test only need two. Additionally, the phylogeny of the populations involved must be well understood in order to interpret a signal of admixture from the 4-population test properly (i.e., to determine which population is admixed). Using weighted LD, on the other hand, largely eliminates the problem of determining the destination or direction of gene flow, since the LD signal of admixture is intrinsic to a specified test population.

**One-reference versus two-reference curves:** In practice, it is often useful to compute weighted LD curves using both the one-reference and two-reference techniques, as both can be used for inferences in different situations. Generally, we consider two-reference curves to be more reliable for parameter estimation, since using the test population as one reference is more prone to introduce unwanted signals, such as recent admixture from a different source, non-admixture LD from reduced population size, or undesired population structure among samples. In particular, populations with more complicated histories and additional sources of LD beyond the specifications of our model will often have different estimates of admixture dates with one- and two-reference curves. There is a slight danger that date disagreement can reflect a false-positive admixture signal, but this is very unlikely if both one- and two-reference curves exist beyond the correlated LD threshold (see Appendix 2). Two-reference curves also allow for direct estimation of mixture fractions, although, as discussed above, we prefer instead to use the method of single-reference bounding. Moreover, there are a number of practical considerations that make the one-reference capabilities of *ALDER* desirable. Foremost is the possibility that one may not have a good surrogate available for one of the ancestral mixing populations, as in our Japanese example. Also, while our method of learning about phylogenetic relationships is best suited to two-reference curves because of the simpler form of the amplitude in terms of branch lengths, it is often useful to begin by computing a suite of single-reference curves, both because the data generated will scale linearly with the

number of references available and because observing a range of different amplitudes gives an immediate signal of the presence of admixture in the test population.

Overall, then, a sample sequence for applying *ALDER* to a new data set might be as follows: (1) test all populations for admixture using all pairs of references from among the other populations; (2) explore admixed populations of interest by comparing single-reference weighted LD curves; (3) learn more detail by analyzing selected two-reference curves alongside the one-reference ones; (4) estimate parameters using one- or two-reference curves as applicable. Of course, step (1) itself involves the complementary usefulness of both one- and two-reference weighted LD, since our test for admixture requires the presence of exponential decay signals in both types of curves.

**Effect of multiple-wave or continuous admixture:** As discussed in our section on robustness of results, in the course of our data analysis, we observed that the weighted LD date estimate almost always becomes more recent when the exponential decay curve is fit for a higher starting distance $d_0$. Most likely, this is because admixtures in human populations have taken place over multiple generations, such that our estimated times represent intermediate dates during the process. To whatever extent an admixture event is more complicated than posited in our point-admixture model, removing low-$d$ bins will lead the fitting to capture proportionately more of the more recent admixture. By default, *ALDER* sets $d_0$ to be the smallest distance such that non-admixture LD signals can be confidently discounted for $d > d_0$ (see Methods (Testing for admixture) and Appendix 2), but it should be noted that the selected $d_0$ will vary for different sets of populations, and in each case the true admixture signal at $d < d_0$ will also be excluded. Theoretically, this pattern could allow us to learn more about the true admixture history of a population, since the value of $a(d)$ at each $d$ represents a particular function of the amount of admixture that took place at each generation in the past. However, in our experience, fitting becomes difficult for any model involving more than two or three parameters. Thus, we made the decision to restrict ourselves to assuming a single point admixture, fit for a principled threshold $d > d_0$, accepting that the inferred date $n$ represents some form of average value over the true history.

**Other possible complications:** In our derivations, we have assumed implicitly that the mixing populations and the reference populations are related through a simple tree. However, it may be that their history is more complicated, for example involving additional admixtures. In this case, our formulas for the amplitude of the ALD curve will be inaccurate if, for example, $A$ and $A'$ have different admixture histories. However, if our assumptions are violated only by events occurring before the divergences between the mixing populations and the corresponding references, then the amplitude will be unaffected. Moreover, no matter what the population history, as long as $A$ and $B$ are free of measurable LD (so that our assumption of independence of alleles conditional on a single ancestry is valid), there will be no effect on the estimated date of admixture.

**Conclusions and future directions:** In this study, we have shown how linkage disequilibrium (LD) generated by population admixture can be a powerful tool for learning about history, extending previous work that showed how it can be used for estimating dates of mixture (MOORJANI *et al.* 2011; PATTERSON *et al.* 2012). We have developed a new suite of tools, implemented in the *ALDER* software package, that substantially increases the speed of admixture LD analysis, improves the robustness of admixture date inference, and exploits the amplitude of LD as a novel source of information about history. In particular, (a) we show how admixture LD can be leveraged into a formal test for mixture that can sometimes find evidence of mixture not detectable by other methods, (b) we show how to estimate mixture proportions, and (c) we show that we can even use this information to infer phylogenetic relationships. A limitation of *ALDER* at present, however, is that it is designed for a model of pulse admixture between two ancestral populations. An important direction for future work will be to generalize similar ideas to make inferences about the time course of admixture in the case that it took place over a longer period of time (POOL and NIELSEN 2009; GRAVEL 2012) and to study multi-way admixture. In addition, it would be valuable to be able to use the information from admixture LD to constrain models of history for multiple populations simultaneously, either by extending *ALDER* itself or by using LD-based test results in conjunction with methods for fitting phylogenies incorporating admixture (PATTERSON

*et al.* 2012; PICKRELL and PRITCHARD 2012; LIPSON *et al.* 2012).

## SOFTWARE

Executable and C++ source files for our *ALDER* software package are available online at the Berger and Reich Lab websites: `http://groups.csail.mit.edu/cb/alder/`, `http://genetics.med.harvard.edu/reich/Reich_Lab/Software.html`.

## ACKNOWLEDGMENTS

M.L. and P.L. acknowledge NSF Graduate Research Fellowship support. N.P., J.P. and D.R. are grateful for support from NSF HOMINID grant #1032255 and NIH grant GM100233.

## APPENDIX 1: DERIVATIONS OF WEIGHTED LD FORMULAS

**Expected weighted LD using two diverged reference populations:** We now derive equation (6) for the expected weighted LD using references $A'$ and $B'$ in place of $A$ and $B$, retaining the notation of Figure S1. Let $A'$ and $B'$ have allele frequencies $p_{A'}(\cdot)$ and $p_{B'}(\cdot)$, and let $\delta'(\cdot) := p_{A'}(\cdot) - p_{B'}(\cdot)$ denote the allele frequency divergences with which we weight the LD $z(x, y)$, giving the two-site statistic

$$a(d) := z(x, y)\delta'(x)\delta'(y).$$

(For brevity, we drop the binning procedure of averaging over SNP pairs $(x, y)$ at distance $|x-y| \approx d$ here.) The value of the random variable $z(x, y)$ is affected by sampling noise as well as genetic drift between $A$ and $B$, while the random variables $\delta'(x)$ and $\delta'(y)$ are outcomes of genetic drift between $A'$ and $B'$. These random variables are uncorrelated conditional on the allele frequencies of $x$ and $y$ in $A''$ and $B''$. We also assume that $x$ and $y$ are distant enough to have negligible background LD and hence the drifts at the two sites are independent. We then have

$$\begin{aligned} E[a(d)] &= E[z(x, y)\delta'(x)\delta'(y)] \\ &= E[E[z(x, y)\delta'(x)\delta'(y) \mid p_{A''}(x), p_{B''}(x), p_{A''}(y), p_{B''}(y)]] \\ &= E[2\alpha\beta\delta(x)\delta(y)\delta'(x)\delta'(y)e^{-nd}] \\ &= 2\alpha\beta e^{-nd} F_2(A'', B'')^2, \end{aligned}$$

where in the last step the relation $E[\delta(x)\delta'(x)] = E[\delta(y)\delta'(y)] = F_2(A'', B'')$ follows from the fact that the intersection of the drift paths $\delta(\cdot)$ and $\delta'(\cdot)$ is the branch between $A''$ and $B''$.

**Expected weighted LD using one diverged reference population:** Using the admixed population $C$ as one reference and a population $A'$ as the other, we have $p_C(\cdot) = \alpha p_A(\cdot) + \beta p_B(\cdot)$ (assuming negligible post-admixture drift), giving weights

$$\delta_{A'C}(\cdot) = p_{A'}(\cdot) - \alpha p_A(\cdot) - \beta p_B(\cdot) = \alpha\delta_{A'A}(\cdot) + \beta\delta_{A'B}(\cdot),$$

where $\delta_{PQ}$ denotes the allele frequency difference between populations $P$ and $Q$. Arguing as above, the expected weighted LD is given by

$$E[a(d)] = E[2\alpha\beta\delta(x)\delta(y)\delta_{A'C}(x)\delta_{A'C}(y)e^{-nd}].$$

To complete the calculation, we compute

$$E[\delta(\cdot)\delta_{A'C}(\cdot)] = \alpha E[\delta(\cdot)\delta_{A'A}(\cdot)] + \beta E[\delta(\cdot)\delta_{A'B}(\cdot)].$$

For the first term, the intersection of the $A$–$B$ and $A'$–$A$ drift paths is the $A$–$A''$ branch, so $E[\delta(\cdot)\delta_{A'A}(\cdot)] = -F_2(A, A'')$ with the negative sign arising because the paths traverse this branch in opposite directions. For the second term, the intersection of the $A$–$B$ and $A'$–$B$ drift paths is the $A''$–$B$ branch (traversed in the same direction), so $E[\delta(\cdot)\delta_{A'B}(\cdot)] = F_2(B, A'')$. Combining these results gives equation (8), as desired. (Note that a slight subtlety arises now that we are using population $C$ in our weights: sites $x$ and $y$ can exhibit admixture LD at appreciable distances, so $\delta_{A'C}(x)$ and $\delta_{A'C}(y)$ are not independent. However, only the drift since admixture is correlated, which is negligible for typical scenarios we study in which admixture occurred 200 or fewer generations ago.)

**Bounding mixture fractions using one reference:** We now establish our claim in the main text that the estimator $\hat{\alpha}$ given in equation (12) for the mixture fraction $\alpha$ is a lower bound when the reference population $A'$ is diverged from $A$. Equation (12) gives a correct estimate when $A' = A$ but becomes an approximation when there is genetic drift between $A$ and $A'$ or between $C$ and $C'$. (For accuracy, in this section we relax our usual assumption that $C = C'$.)

Rearranging equation (12), we have by definition

$$\frac{2\hat{\alpha}}{1-\hat{\alpha}} := \frac{\hat{a}_0}{F_2(A', C')^2}. \tag{13}$$

From equation (7), the amplitude $\hat{a}_0$ is in truth given by

$$\hat{a}_0 = 2\alpha\beta(-\alpha F_2(A, A'') + \beta F_2(B, A''))^2 e^{-n/2N_e},$$

where we have included the post-admixture drift multiplier $e^{-n/2N_e}$ from the $C$–$C'$ branch. It follows that

$$\frac{\hat{a}_0}{(-\alpha\beta F_2(A,A'')+\beta^2 F_2(B,A''))^2} = \frac{2\alpha}{\beta}e^{-n/2N_e} < \frac{2\alpha}{1-\alpha}. \tag{14}$$

We claim that $F_2(A',C')^2 > (-\alpha\beta F_2(A,A'')+\beta^2 F_2(B,A''))^2$, in which case combining (13) and (14) gives $\hat{\alpha}/(1-\hat{\alpha}) < \alpha/(1-\alpha)$ and hence $\hat{\alpha} < \alpha$. Indeed, we have

$$\begin{aligned} F_2(A',C') &> F_2(A'',C) \\ &= \alpha^2 F_2(A,A'') + \beta^2 F_2(B,A'') \\ &> -\alpha\beta F_2(A,A'') + \beta^2 F_2(B,A''). \end{aligned}$$

Squaring both sides appears to give our claim, but we must be careful because it is possible for the final expression to be negative. We will assume $A'$ is closer to $A$ than $B$, i.e., $F_2(A,A'') < F_2(B,A'')$. Then, if $\alpha < \beta$, the final expression is clearly positive. If $\alpha > \beta$, we have $\alpha^2 F_2(A,A'') > \alpha\beta F_2(A,A'')$ and so

$$F_2(A',C') > \alpha^2 F_2(A,A'') + \beta^2 F_2(B,A'') > \alpha\beta F_2(A,A'') - \beta^2 F_2(B,A'').$$

Thus, squaring the inequality is valid in either case, establishing our bound. From the above we also see that the accuracy of the bound depends on the sizes of the terms that are lost in the approximation—$\alpha F_2(A,A'')$, $F_2(A',A'')$ and $F_2(C,C')$—relative to the term that is kept, $\beta^2 F_2(B,A'')$. In particular, aside from the bound being tighter the closer $A'$ is to $A$, it is also more useful when the reference $A'$ comes from the minor side $\alpha < 0.5$.

**Affine term from assortative mating:** In the above, we have assumed that population $C$ is homogeneously admixed; i.e., an allele in any random admixed individual from $C$ has a fixed probability $\alpha$ of having ancestry from $A$ and $\beta$ of having ancestry from $B$. In practice, many admixed populations experience assortative mating such that subgroups within the population have varying amounts of each ancestry. Heterogeneous admixture among subpopulations creates LD that is independent of genetic distance and not broken down by recombination: intuitively, knowing the

value of an allele in one individual changes the prior on the ancestry proportions of that individual, thereby providing information about all other alleles (even those on other chromosomes). This phenomenon causes weighted LD curves to exhibit a nonzero horizontal asymptote, the form of which we now derive.

We model assortative mating by taking $\alpha$ to be a random variable rather than a fixed probability, representing the fact that individuals from different subpopulations of $C$ have different priors on their $A$ ancestry. As before we set $\beta := 1 - \alpha$ and we now denote by $\bar{\alpha}$ and $\bar{\beta}$ the population-wide mean ancestry proportions; thus, $\mu_x = \bar{\alpha} p_A(x) + \bar{\beta} p_B(x)$. We wish to compute the expected diploid covariance $E[z(x, y)]$ which we saw in equation (2) splits into four terms corresponding to the LD between each copy of the $x$ allele and each copy of the $y$ allele.

Previously, the cross-terms $\text{cov}(X_1, Y_2) + \text{cov}(X_2, Y_1)$ vanished because a homogeneously mixed population does not exhibit inter-chromosome LD. Now, however, we have

$$\begin{aligned}
&E[(X_1 - \mu_x)(Y_2 - \mu_y) \mid p(A \text{ ancestry}) = \alpha] \\
&\quad = \quad E[X_1 - \mu_x \mid p(A \text{ ancestry}) = \alpha] \cdot E[Y_2 - \mu_y \mid p(A \text{ ancestry}) = \alpha] \\
&\quad = \quad (\alpha p_A(x) + \beta p_B(x) - \mu_x)(\alpha p_A(y) + \beta p_B(y) - \mu_y) \\
&\quad = \quad ((\alpha - \bar{\alpha}) p_A(x) + (\beta - \bar{\beta}) p_B(x))((\alpha - \bar{\alpha}) p_A(y) + (\beta - \bar{\beta}) p_B(y)) \\
&\quad = \quad ((\alpha - \bar{\alpha}) p_A(x) - (\alpha - \bar{\alpha}) p_B(x))((\alpha - \bar{\alpha}) p_A(y) - (\alpha - \bar{\alpha}) p_B(y)) \\
&\quad = \quad (\alpha - \bar{\alpha})^2 \delta(x) \delta(y).
\end{aligned}$$

It follows that

$$\text{cov}(X_1, Y_2) = E[(\alpha - \bar{\alpha})^2 \delta(x) \delta(y)] = \text{var}(\alpha) \delta(x) \delta(y) \tag{15}$$

and likewise for $\text{cov}(X_2, Y_1)$.

To compute the same-chromosome covariance terms, we split into two cases according to whether or not recombination has occurred between $x$ and $y$ since admixture. In the case that recombination has not occurred—i.e., the ancestry of the chromosomal region between $x$ and $y$ can be traced back as one single chunk to the time of admixture, which occurs with probability

$e^{-nd}$—the region from $x$ to $y$ has ancestry from $A$ with probability $\alpha$ and from $B$ with probability $\beta$. Thus,

$$\begin{aligned}
&E[(X_1-\mu_x)(Y_1-\mu_y) \mid \text{no recomb}, p(A \text{ ancestry}) = \alpha] \\
&= \alpha E[(X_1-\mu_x)(Y_1-\mu_y) \mid A \text{ ancestry}] + \beta E[(X_1-\mu_x)(Y_1-\mu_y) \mid B \text{ ancestry}] \\
&= \alpha(p_A(x)-\mu_x)(p_A(y)-\mu_y) + \beta(p_B(x)-\mu_x)(p_B(y)-\mu_y) \\
&= \alpha(\bar{\beta}p_A(x) - \bar{\beta}p_B(x))(\bar{\beta}p_A(y) - \bar{\beta}p_B(y)) + \beta(\bar{\alpha}p_B(x) - \bar{\alpha}p_a(x))(\bar{\alpha}p_B(y) - \bar{\alpha}p_A(y)) \\
&= (\alpha\bar{\beta}^2 + \beta\bar{\alpha}^2)\delta(x)\delta(y).
\end{aligned}$$

Taking the expectation over the whole population,

$$E[(X_1-\mu_x)(Y_1-\mu_y) \mid \text{no recomb}] = (\bar{\alpha}\bar{\beta}^2 + \bar{\beta}\bar{\alpha}^2)\delta(x)\delta(y) = \bar{\alpha}\bar{\beta}\delta(x)\delta(y) \tag{16}$$

as without assortative mating.

In the case where there has been a recombination, the loci are independent conditioned upon the ancestry proportion $\alpha$, as in our calculation of the cross-terms; hence,

$$E[(X_1-\mu_x)(Y_1-\mu_y) \mid \text{recomb}] = \text{var}(\alpha)\delta(x)\delta(y) \tag{17}$$

occurring with probability $1-e^{-nd}$.

Combining equations (15), (16), and (17), we obtain

$$\begin{aligned}
E[z(x,y)] &= E[(X-\mu_x)(Y-\mu_y)] \\
&= 2\ \text{var}(\alpha)\delta(x)\delta(y) + 2e^{-nd}\bar{\alpha}\bar{\beta}\delta(x)\delta(y) + 2(1-e^{-nd})\text{var}(\alpha)\delta(x)\delta(y) \\
&= (e^{-nd}(2\bar{\alpha}\bar{\beta} - 2\ \text{var}(\alpha)) + 4\ \text{var}(\alpha))\delta(x)\delta(y).
\end{aligned}$$

Importantly, our final expression for $E[z(x,y)]$ still factors as the product of a $d$-dependent term—now an exponential decay plus a constant—and the allele frequency divergences $\delta(x)\delta(y)$. Because it is the product $\delta(x)\delta(y)$ that interacts with our various weighting schemes, the formulas that we have derived for the weighted LD curve $E[a(d)]$—equations (4), (6), (7), and (8)—retain the same factors involving $F_2$ distances and change only in the replacement of $2\alpha\beta e^{-nd}$ with $e^{-nd}(2\bar{\alpha}\bar{\beta} - 2\ \text{var}(\alpha)) + 4\ \text{var}(\alpha)$.

## APPENDIX 2: TESTING FOR ADMIXTURE

Here we provide details of the weighted LD-based test for admixture we implement in *ALDER*. The test procedure is summarized in the main text; we focus here on technical aspects not given explicitly in Methods.

**Determining extent of LD correlation:** The first step of *ALDER* estimates the distance to which LD in the test population is correlated to LD in each reference population. Such correlation suggests shared demographic history that can confound the ALD signal, so it is important to determine the distance to which LD correlation extends and analyze weighted LD curves $\hat{a}(d)$ only for $d$ greater than this threshold. Our procedure is as follows. We successively compute LD correlation for SNP pairs $(x, y)$ within distance bins $d_k < |x - y| < d_{k+1}$, where $d_k = kr$ for some bin resolution $r$ (0.05 cM by default). For each SNP pair $(x, y)$ within a bin, we estimate the LD (i.e., sample covariance between allele counts at $x$ and $y$) in the test population and the LD in the reference population. We then form the correlation coefficient between the test LD estimates and reference LD estimates over all SNP pairs in the bin. We jackknife over chromosomes to estimate a standard error on the correlation, and we set our threshold after the second bin for which the correlation is insignificant ($p > 0.05$). To reduce dependence on sample size, we then repeat this procedure with successively increasing resolutions up to $0.1$ cM and set the final threshold as the maximum of the cutoffs obtained.

**Determining significance of a weighted LD curve:** To define a formal test for admixture based on weighted LD, we need to estimate the significance of an observed weighted LD curve $\hat{a}(d)$. This question is statistically subtle for several reasons. First, the null distribution of the curve $\hat{a}(d)$ is complex. Clearly the test population $C$ should not be admixed under the null hypothesis, but as we have discussed, shared demography—particularly bottlenecks—can also produce weighted LD. We circumvent this issue by using the pre-tests described in the next section and assume that if the test triple $(C; A', B')$ passes the pre-tests, then under the null hypothesis, non-admixture demo-

graphic events have negligible effect on weighted LD beyond the correlation threshold computed above. Even so, the $\hat{a}(d)$ curve still cannot be modeled as random white noise: because SNPs contribute to multiple bins, the curve typically exhibits noticeable autocorrelation. Finally, even if we ignore the issue of colored noise, the question of distinguishing a curve of any type—in our case, an exponential decay—from noise is technically subtle: the difficulty is that a singularity arises in the likelihood surface when the amplitude vanishes, which is precisely the hypothesis that we wish to test (DAVIES 1977).

In light of these considerations, we estimate a $p$-value using the following procedure, which we feel is well-justified despite not being entirely theoretically rigorous. We perform jackknife replicates of the $\hat{a}(d)$ curve computation and fitting, leaving out one chromosome in each replicate, and estimate a standard error for the amplitude and decay constant of the curve using the usual jackknife procedure. We obtain a "$z$-score" for the amplitude and the decay constant by dividing each by its estimated standard error. Finally, we take the minimum (i.e., less-significant) of these $z$-scores and convert it to a $p$-value assuming it comes from a standard normal; we report this $p$-value as our final significance estimate.

Our intuition for this procedure is that checking the "$z$-score" of the decay constant essentially tells us whether or not the exponential decay is well-determined: if the $\hat{a}(d)$ curve is actually just noise, then the fitting of jackknife replicates should fluctuate substantially. On the other hand, if the $\hat{a}(d)$ curve has a stable exponential decay constant, then we have good evidence that $\hat{a}(d)$ is actually well-fit by an exponential—and in particular, the amplitude of the exponential is nonzero, meaning we are away from the singularity. In this case the technical difficulty is no longer an issue and the jackknife estimate of the amplitude should in fact give us a good estimate of a $z$-score that is approximately normal under the null. The "$z$-score" for the decay constant certainly is not normally distributed—in particular, it is always positive—but taking the minimum of these two scores only makes the test more conservative.

Perhaps most importantly, we have compelling empirical evidence that our $z$-scores are well-behaved under the null. We applied our test to nine HGDP populations that neither *ALDER* nor the

3-population test identified as admixed; for each test population, we used as references all populations with correlated LD detectable to no more than 0.5 cM. These test triples thus comprise a suite of approximately null tests. We computed Q-Q plots for the reported $z$-scores and observed that for $z > 0$ (our region of interest), our reported z-scores follow the normal distribution reasonably well, generally erring slightly on the conservative side (Figure S4). These findings give strong evidence that our significance calculation is sufficiently accurate for practical purposes; in reality, model violation is likely to exert stronger effects than the approximation error in our $p$-values, and although our empirical tests cannot probe the tail behavior of our statistic, for practical purposes the precise values of $p$-values less than, say, $10^{-6}$ are generally inconsequential.

**Pre-test thresholds:** To ensure that our test is applicable to a given triple $(C; A', B')$, we need to rule out the possibility of pathological demography producing non-admixture-related weighted LD (Figure S3). We do so by computing the weighted LD curves with weights $A'$–$B'$, $A'$–$C$, and $B'$–$C$ and fitting an exponential to each curve. To eliminate the possibility of a shared ancestral bottleneck between $C$ and one of the references, we check that the three estimated amplitudes and decay constants are well-determined; explicitly, we compute a jackknife-based standard error for each parameter and require the implied $p$-value for the parameter being positive to be less than 0.05. If so, we conclude that whatever LD is present is due to admixture, not other demography, and we report the $p$-value estimate defined above for the significance of the $A'$–$B'$ curve as the $p$-value of our test.

We are aware of one demographic scenario in which the *ALDER* test could potentially return a finding of admixture when the test population is not in fact admixed. As illustrated in Figure S3, this would occur when $A'$ and $C$ have experienced a shared bottleneck and $C$ has subsequently had a further period of low population size. We do not believe that we have ever encountered such a false positive admixture signal, but to guard against it, we note that if it were to occur, the three decay time constants for the reference pairs $A'$–$B'$, $A'$–$C$, and $B'$–$C$ would disagree. Thus, along with the test results, *ALDER* returns a warning whenever the three best-fit values of the decay

constant do not agree to within 25%.

**Multiple-hypothesis correction:** In determining statistical significance of test results when testing a population using many pairs of references, we apply a multiple-hypothesis correction that takes into account the number of tests being run. Because some populations in the reference set may be very similar, however, the tests may not be independent. We therefore compute an effective number $n_r$ of distinct references by running PCA on the allele frequency matrix of the reference populations; we take $n_r$ to be the number of singular values required to account for 90% of the total variance. Finally, we apply a Bonferroni correction to the $p$-values from each test using the effective number $\binom{n_r}{2}$ of reference pairs.

FIGURE LEGENDS

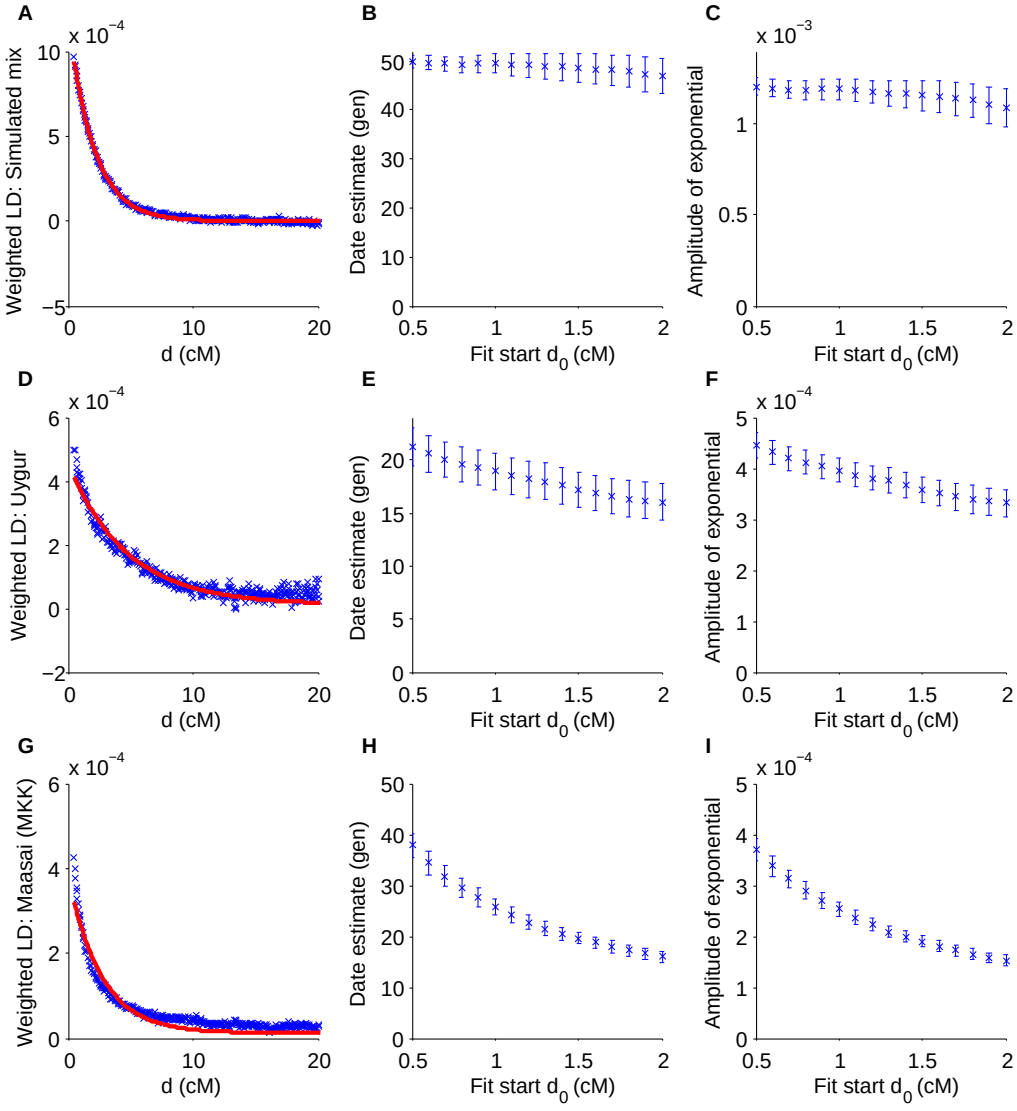

**Figure 1.** Dependence of date estimates and weighted LD amplitudes on fitting start point. Rows correspond to three test scenarios: Simulated 75% YRI / 25% CEU mixture 50 generations ago with Yoruba–French weights (top); Uygur with Han–French weights (middle); HapMap Maasai with Yoruba–French weights (bottom). The left panel of each row shows the weighted LD curve $a(d)$ (blue) with best-fit exponential decay curve (red), fit starting from $d_0 = 0.5$ cM. Remaining panels show the date estimate (middle) and amplitude (right) as a function of $d_0$. (We note that our date estimates for Uygur are somewhat more recent than those in Patterson et al. (2012), most likely because of our direct estimate of the affine term in the weighted LD curve.)

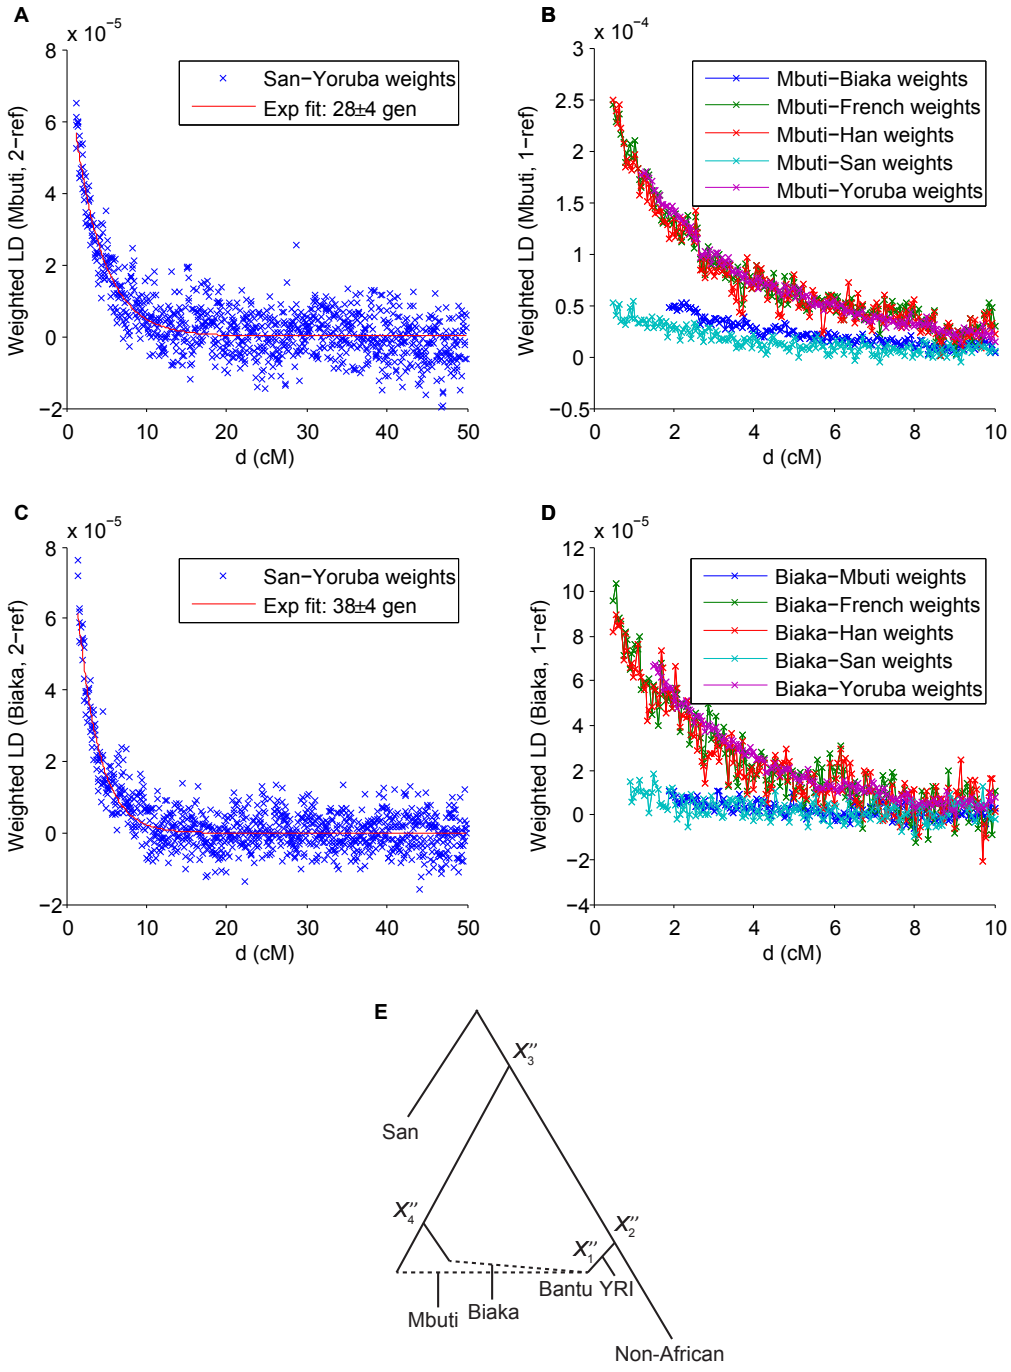

**Figure 2.** Weighted LD curves for Mbuti using San and Yoruba as reference populations (A) and using Mbuti itself as one reference and several different second references (B). Analogous curves for Biaka (C, D) swapping the roles of Mbuti and Biaka. Genetic distances are discretized into bins at 0.05 cM resolution. Data for each curve are plotted and fit (A, C) starting from the corresponding *ALDER*-computed LD correlation thresholds. Different amplitudes of one-reference curves (B, D) imply different phylogenetic positions of the references relative to the true mixing populations, suggesting a sketch of a putative admixture graph for Mbuti (E). Relative branch lengths are qualitative, and the true root is not necessarily as depicted.

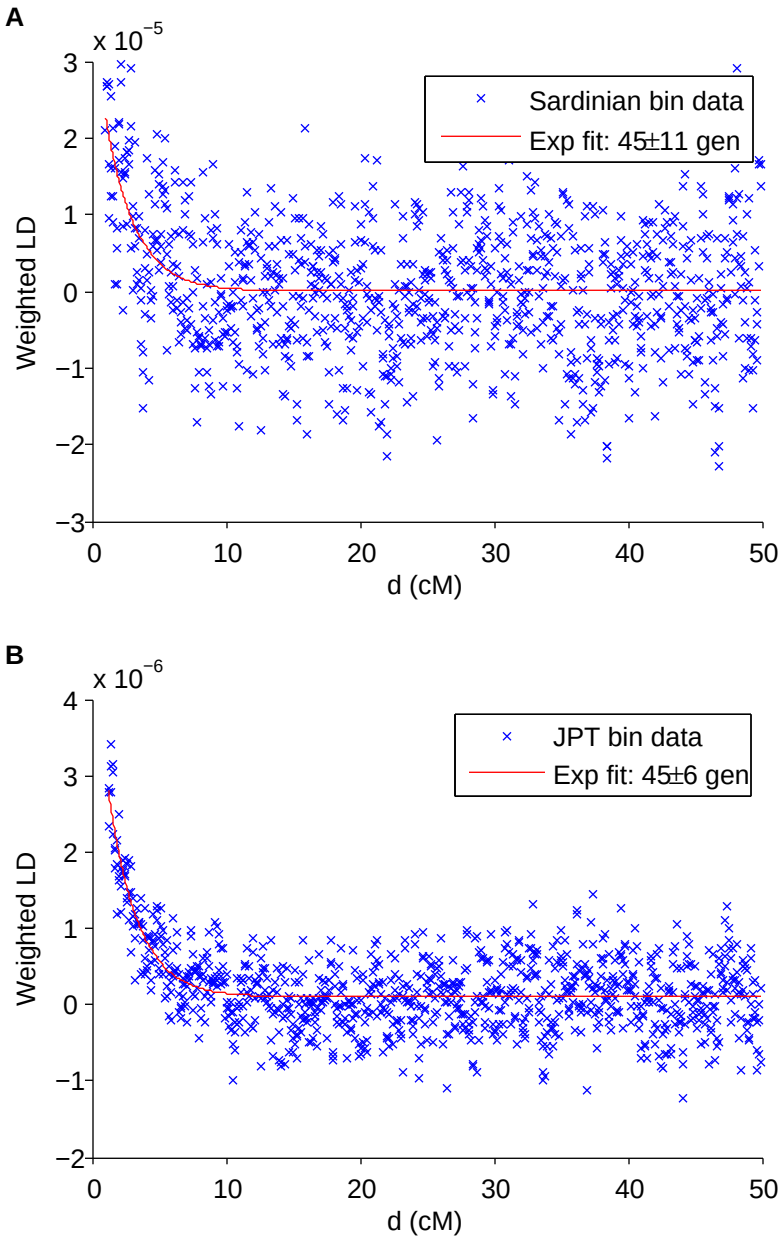

**Figure 3.** Weighted LD curves for HGDP Sardinian using Italian–Yoruba weights (A) and HapMap Japanese (JPT) using JPT itself as one reference and HapMap Han Chinese (CHB) as the second reference (B).

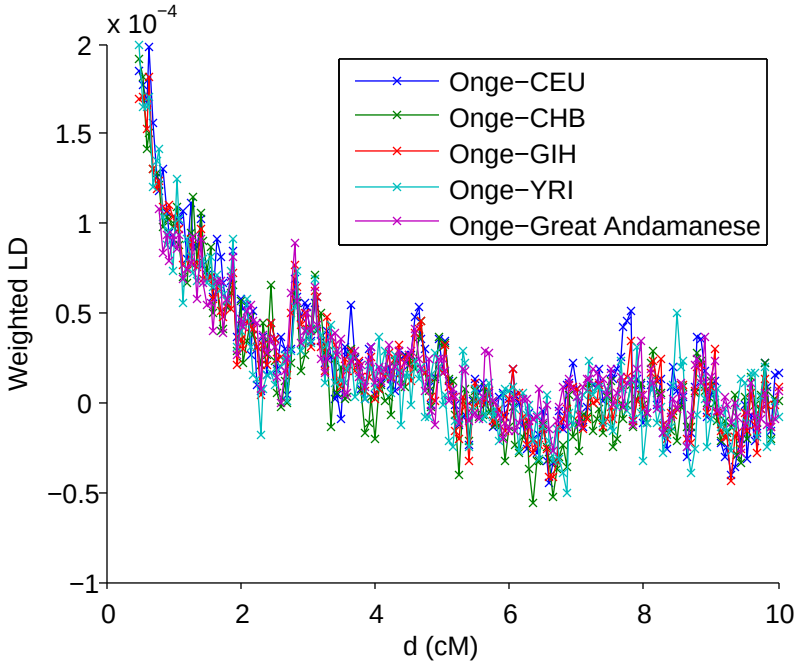

**Figure 4.** Weighted LD curves for Onge using Onge itself as one reference and several different second references.

We ran both *ALDER* and the 3-population test for admixture on each of the 53 HGDP populations using all pairs of other populations as references. We group the populations according to whether or not each test methodology produces at least one test identifying them as admixed; for each population, we list the number of reference pairs with which with each method (abbreviated "LD"

**Table 2. Amplitudes and dates from weighted LD curves with Sardinian using various reference pairs.**

| Ref 1 | Ref 2 | Weighted LD amplitude | Date estimate |
|---|---|---|---|
| CEU | YRI | 0.00003192 $\pm$ 0.00000903 | 48 $\pm$ 10 |
| CHB | YRI | 0.00001738 $\pm$ 0.00000679 | 34 $\pm$ 8 |
| CEU | CHB | 0.00000873 $\pm$ 0.00000454 | 52 $\pm$ 21 |

Data are shown from *ALDER* fits to weighted LD curves computed using Sardinian as the test population and pairs of HapMap CEU, YRI, CHB as the references. We omitted chromosome 8 from the analysis because of anomalous long-range LD. Curves $a(d)$ were fit for $d > 1.2$ cM, the extent of LD correlation between Sardinian and CEU computed by *ALDER*.

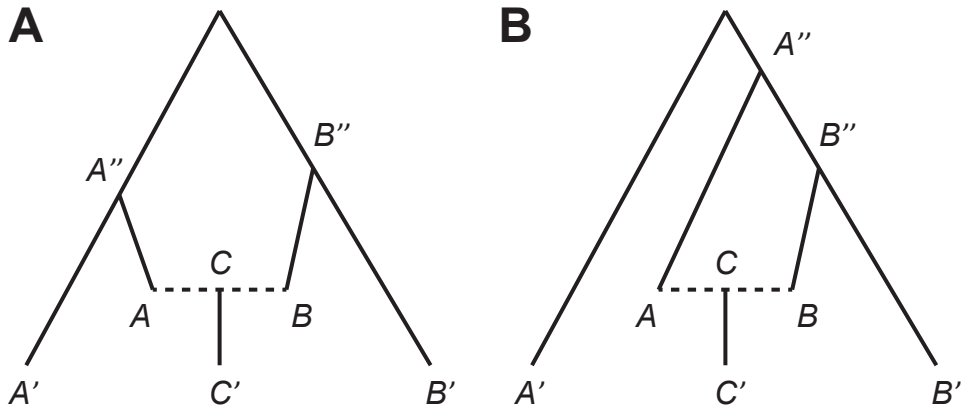

**Figure S1.** Notational diagram of phylogeny containing admixed population and references. Population $C'$ is descended from an admixture between $A$ and $B$ to form $C$; populations $A'$ and $B'$ are present-day references. In practice, we assume that post-admixture drift is negligible and $C' = C$. The branch points of $A'$ and $B'$ from the $A$–$B$ lineage are marked $A''$ and $B''$; note that in a rooted phylogeny, these need not be most recent common ancestors.

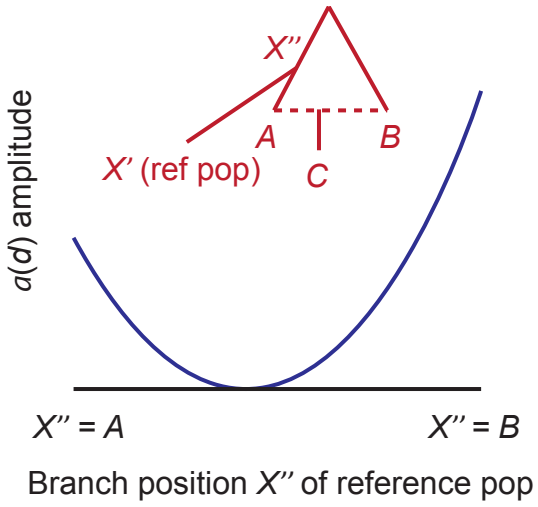

**Figure S2.** Dependence of single-reference weighted LD amplitude on the reference population. When taking weights as allele frequency differences between the admixed population and a single reference population $X'$, the weighted LD curve $a(d)$ has expected amplitude proportional to $(\alpha F_2(A, X'') - \beta F_2(B, X''))^2$, where $X''$ is the point along the $A$–$B$ lineage at which the reference population branches. Note in particular that as $X''$ varies from $A$ to $B$, the amplitude traces out a parabola that starts at $\beta^2 F_2(A, B)^2$, decreases to a minimum value of 0, and increases to $\alpha^2 F_2(A, B)^2$.

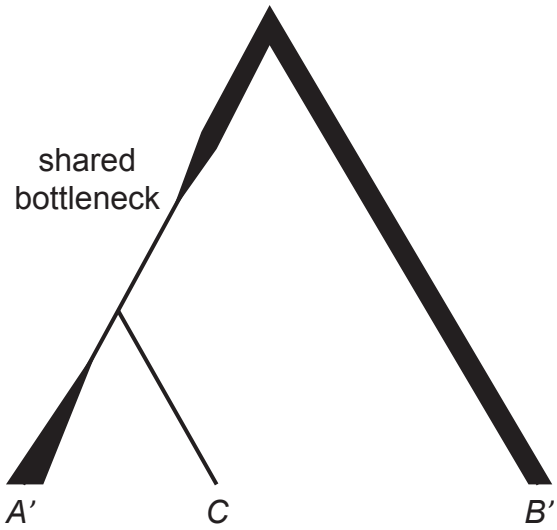

**Figure S3.** Non-admixture-related demography producing weighted LD curves. The test population is $C$ and references are $A'$ and $B'$; the common ancestor of $A'$ and $C$ experienced a recent bottleneck from which $C$ has not yet recovered, leaving long-range LD in $C$ that is potentially correlated to all three possible weighting schemes ($A'$–$B'$, $A'$–$C$, and $B'$–$C$).

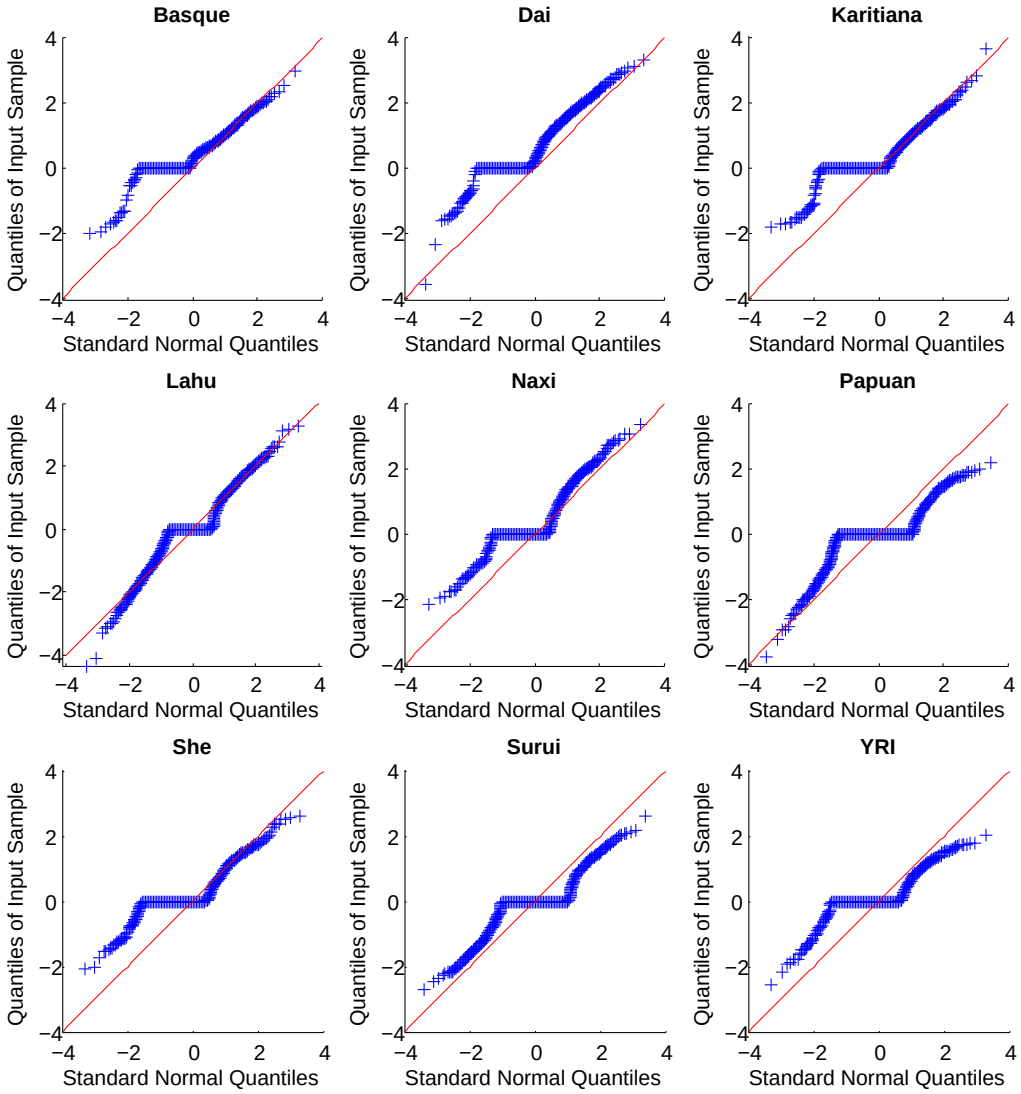

**Figure S4.** Q-Q plots comparing *ALDER* $z$-scores to standard normal on null examples. We show results from nine HGDP populations that neither *ALDER* nor the 3-population test found to be admixed. We are interested in values of $z > 0$; the Q-Q plots show that these values follow the standard normal reasonably well, tending to err on the conservative side.

| 10 | 12±1 | 20±2 | 54±4 | 110±15 | 265±55 |
| 20 | 12±1 | 21±1 | 52±4 | 131±15 | 234±33 |
| 50 | 11±0 | 20±1 | 53±4 | 122±8 | 221±23 |
| 100 | 11±0 | 20±0 | 53±3 | 109±5 | 219±10 |

We simulated scenarios in which admixture occurred 10, 20, 50, 100, or 200 generations ago and show results from runs of *ALDER* using varying numbers of admixed samples. Note that standard errors shown are *ALDER*'s jackknife estimates of its own error on a single simulation (not standard errors from averaging over multiple simulations).

**Table S9.** Effect of SNP ascertainment on date estimates.

| Mixed pop | Ref 1 | Ref 2 | French asc | Han asc | San asc | Yoruba asc |
|---|---|---|---|---|---|---|
| Burusho | French | Han | 47±12 | 51±13 | 56±10 | 41±10 |
| Uygur | French | Han | 15±2 | 14±2 | 13±2 | 16±2 |
| Hazara | French | Han | 22±2 | 22±3 | 23±2 | 22±3 |

| Bedouin | French | Yoruba | 27±3 | 23±3 | 23±3 | 24±3 |
| MbutiPygmy | San | Yoruba | 33±12 | 33±6 | 41±14 | 30±8 |
| BiakaPygmy | San | Yoruba | 39±6 | 50±14 | 35±6 | 36±7 |

We compared dates of admixture estimated by *ALDER* on a variety of test triples from the HGDP using SNPs ascertained as heterozygous in full genome sequences of one French, Han, San, and Yoruba individual (Panels 1, 2, 4, and 5 of the Affymetrix Human Origins Array (PATTERSON *et al.* 2012)). Standard errors are from a jackknife over the 22 autosomes.

Mathematica code and output are shown for computing the polyache statistic that estimates the one-reference weighted LD, $E[(X-\mu_x)(Y-\mu_y)(\mu_x-p_A(x))(\mu_y-p_A(y))]$, where $p_A(\cdot)$ are allele frequencies of the single reference population and $\mu_x$ and $\mu_y$ denote allele frequencies of the admixed population. In the above, $S_0^{(k)} := m(m-1)\cdots(m-k+1)$ and $S_{r,s} := \sum_{i=1}^{m} X_i^r Y_i^s$, where $m$ is the number of admixed samples and $i$ ranges over the admixed individuals, which have allele counts $X_i$ and $Y_i$ at sites $x$ and $y$.

**File S2. FFT computation of weighted LD.**

In this note we describe how to compute weighted LD (aggregated over distance bins) in time

$$O(m(S + B \log B)),$$

where $m$ is the number of admixed individuals, $S$ is the number of SNPs, and $B$ is the number of bins needed to span the chromosomes. In contrast, the direct method of computing pairwise LD for each individual SNP pair requires $O(mS^2)$ time. In practice our approach offers speedups of over 1000x on typical data sets. We further describe a similar algorithm for computing the single-reference weighted LD polyache statistic that runs in time

$$O(m^2(S + B \log B))$$

with the slight trade-off of ignoring SNPs with missing data.

Our method consists of three key steps: (1) split and factorize the weighted LD product; (2) group factored terms by bin; and (3) apply fast Fourier transform (FFT) convolution. As a special case of this approach, the first two ideas alone allow us to efficiently compute the affine term (i.e., horizontal asymptote) of the weighted LD curve using inter-chromosome SNP pairs.

## TWO-REFERENCE WEIGHTED LD

We first establish notation. Say we have an $S \times m$ genotype array $\{c_{x,i}\}$ from an admixed population. Assume for now that there are no missing values, i.e.,

$$c_{x,i} \in \{0, 1, 2\}$$

for $x$ indexing SNPs by position on a genetic map and $i = 1, \ldots, m$ indexing individuals. Given a set of weights $w_x$, one per SNP, we wish to compute weighted LD of SNP pairs aggregated by inter-SNP distance $d$:

$$R(d) := \sum_{\substack{|x-y| \approx d \\ x<y}} D_2(x, y) w_x w_y = \frac{1}{2} \sum_{|x-y| \approx d} D_2(x, y) w_x w_y$$

where $D_2$ is the sample covariance between genotypes at $x$ and $y$, the diploid analog of the usual LD measure $D$:

$$\begin{aligned} D_2(x,y) &:= \frac{1}{m-1}\sum_{i=1}^{m} c_{x,i}c_{y,i} - \frac{1}{m(m-1)}\sum_{i=1}^{m} c_{x,i}\sum_{j=1}^{m} c_{y,j} \\ &= \frac{1}{m-1}\sum_{i=1}^{m} c_{x,i}c_{y,i} - \frac{1}{m(m-1)} s_x s_y, \end{aligned} \tag{1}$$

where we have defined

$$s_x := \sum_{i=1}^{m} c_{x,i}.$$

Substituting for $D_2(x,y)$, we have

$$\begin{aligned} R(d) &= \frac{1}{2}\sum_{|x-y|\approx d}\left(\frac{1}{m-1}\sum_{i=1}^{m} c_{x,i}c_{y,i} - \frac{1}{m(m-1)} s_x s_y\right) w_x w_y \\ &= \left(\sum_{i=1}^{m}\frac{1}{2(m-1)}\sum_{|x-y|\approx d} c_{x,i}w_x \cdot c_{y,i}w_y\right) - \frac{1}{2m(m-1)}\sum_{|x-y|\approx d} s_x w_x \cdot s_y w_y. \end{aligned} \tag{2}$$

We have thus rewritten $R(d)$ as a linear combination of $m+1$ terms of the form

$$\sum_{|x-y|\approx d} f(x)f(y).$$

(The sum over $i$ consists of $m$ such terms, and the final term accounts for one more.)

In general, sums of the form

$$\sum_{|x-y|\approx d} f(x)g(y)$$

can be efficiently computed by convolution if we first discretize the genetic map on which the SNP positions $x$ and $y$ lie. For notational convenience, choose the distance scale such that a unit distance corresponds to the desired bin resolution. We will compute

$$\sum_{\lfloor x\rfloor - \lfloor y\rfloor = d} f(x)g(y). \tag{3}$$

That is, we divide the chromosome into bins of unit distance and aggregate terms $f(x)g(y)$ by the distance between the bin centers of $x$ and $y$. Note that this procedure does not produce exactly the same result as first subtracting the genetic positions and then binning by $|x-y|$: with our approach,

pairs $(x, y)$ that map to a given bin can have actual distances that are off by as much as one full bin width, versus half a bin width with the subtract-then-bin approach. However, we can compensate simply by doubling the bin resolution.

To compute expression (3), we write

$$\begin{aligned}\sum_{\lfloor x\rfloor-\lfloor y\rfloor=d} f(x)g(y) &= \sum_{b=0}^{B}\sum_{\lfloor x\rfloor=b}\sum_{\lfloor y\rfloor=b-d} f(x)g(y) \\ &= \sum_{b=0}^{B}\left(\sum_{\lfloor x\rfloor=b} f(x)\right)\left(\sum_{\lfloor y\rfloor=b-d} g(y)\right). \qquad (4)\end{aligned}$$

Writing

$$F(b) := \sum_{\lfloor x\rfloor=b} f(x), \quad G(b) := \sum_{\lfloor x\rfloor=b} g(x),$$

expression (4) becomes

$$\sum_{b=0}^{B} F(b)G(b-d) = (F \star G)(d),$$

a cross-correlation of binned $f(x)$ and $g(y)$ terms.

Computationally, binning $f$ and $g$ to form $F$ and $G$ takes $O(S)$ time, after which the cross-correlation can be performed in $O(B \log B)$ time with a fast Fourier transform. The full computation of the $m + 1$ convolutions in equation (2) thus takes $O(m(S + B \log B))$ time. In practice we often have $B \log B < S$, in which case the computation is linear in the data size $mS$.

One additional detail is that we usually want to compute the average rather than the sum of the weighted LD contributions of the SNP pairs in each bin; this requires normalizing by the number of pairs $(x, y)$ that map to each bin, which can be computed in an analogous manner with one more convolution (setting $f \equiv 1$, $g \equiv 1$). Finally, we note that our factorization and binning approach immediately extends to computing weighted LD on inter-chromosome SNP pairs (by putting all SNPs in a chromosome in the same bin), which allows robust estimation of the horizontal asymptote of the weighted LD curve.

**Missing Data** The calculations above assumed that the genotype array contained no missing data, but in practice a fraction of the genotype values may be missing. The straightforward non-FFT

computation has no difficulty handling missing data, as each pairwise LD term $D_2(x, y)$ can be calculated as a sample covariance over just the individuals successfully genotyped at both $x$ and $y$. Our algebraic manipulation runs into trouble, however, because if $k$ individuals have a missing value at either $x$ or $y$, then the sample covariance contains denominators of the form $1/(m-k-1)$ and $1/(m-k)(m-k-1)$—and $k$ varies depending on $x$ and $y$.

One way to get around this problem is simply to restrict the analysis to sites with no missing values at the cost of slightly reduced power. If a fraction $p$ of the SNPs contain at least one missing value, this workaround reduces the number of SNP pairs available to $(1-p)^2$ of the total, which is probably already acceptable in practice.

We can do better, however: in fact, with a little more algebra (but no additional computational complexity), we can include all pairs of sites $(x, y)$ for which at least one of the SNPs $x$, $y$ has no missing values, bringing our coverage up to $1 - p^2$.

We will need slightly more notation. Adopting `eigenstrat` format, we now let our genotype array consist of values

$$c_{x,i} \in \{0, 1, 2, 9\}$$

where 9 indicates a missing value. (Thus, $\{c_{x,i}\}$ is exactly the data that would be contained in a `.geno` file.) For convenience, we write

$$c^{(0)}_{x,i} := \begin{cases} c_{x,i} & \text{if } c_{x,i} \in \{0, 1, 2\} \\ 0 & \text{otherwise.} \end{cases}$$

That is, $c^{(0)}_{x,i}$ replaces missing values with 0s. As before we set

$$s_x := \sum_{i : c_{x,i} \neq 9} c_{x,i} = \sum_{i=1}^{m} c^{(0)}_{x,i}$$

to be the sum of all non-missing values at $x$, which also equals the sum of all $c^{(0)}_{x,i}$ because the missing values have been 0-replaced. Finally, define

$$k_x := \#\{i : c_{x,i} = 9\}$$

to be the number of missing values at site $x$.

We now wish to compute aggregated weighted LD over pairs $(x, y)$ for which at least one of $k_x$ and $k_y$ is 0. Being careful not to double-count, we have:

$$\begin{aligned} R(d) &:= \sum_{\substack{|x-y|\approx d \\ x<y \\ k_x=0 \text{ or } k_y=0}} D_2(x,y) w_x w_y \\ &= \frac{1}{2} \sum_{\substack{|x-y|\approx d \\ k_x=0 \text{ and } k_y=0}} D_2(x,y) w_x w_y + \sum_{\substack{|x-y|\approx d \\ k_x=0 \text{ and } k_y\neq 0}} D_2(x,y) w_x w_y \\ &= \sum_{|x-y|\approx d} \frac{I[k_x=0]}{1+I[k_y=0]} D_2(x,y) w_x w_y, \end{aligned} \tag{5}$$

where the shorthand $I[\cdot]$ denotes a $\{0, 1\}$-indicator.

Now, for a pair of sites $(x, y)$ where $x$ has no missing values and $y$ has $k_y$ missing values,

$$D_2(x,y) = \frac{1}{m-k_y-1} \sum_{i=1}^{m} c_{x,i} c_{y,i}^{(0)} - \frac{1}{(m-k_y)(m-k_y-1)} \left( s_x - \sum_{i=1}^{m} I[c_{y,i}=9] c_{x,i} \right) s_y. \tag{6}$$

Indeed, we claim the above equation is actually just a rewriting of the standard covariance formula (1), appropriately modified now that the covariance is over $m - k_y$ values rather than $m$:

- In the sum $\sum_{i=1}^{m} c_{x,i} c_{y,i}^{(0)}$, missing values in $y$ have been 0-replaced, so those terms vanish and the sum effectively consists of the desired $m - k_y$ products $c_{x,i} c_{y,i}$.
- Similarly, $s_y$ is equal to the sum of the $m - k_y$ non-missing $c_{y,i}$ values.
- Finally, $s_x - \sum_{i=1}^{m} I[c_{y,i} = 9] c_{x,i}$ represents the sum of $c_{x,i}$ over individuals $i$ successfully genotyped at $y$, written as the sum $s_x$ over all $m$ individuals minus a correction.

Substituting (6) into expression (5) for $R(d)$ and rearranging, we have

$$\begin{aligned} R(d) &= \sum_{|x-y|\approx d} \frac{I[k_x=0]}{1+I[k_y=0]} \left( \frac{1}{m-k_y-1} \sum_{i=1}^{m} c_{x,i} c_{y,i}^{(0)} \right. \\ &\qquad \left. - \frac{1}{(m-k_y)(m-k_y-1)} \left( s_x - \sum_{i=1}^{m} I[c_{y,i}=9] c_{x,i} \right) s_y \right) w_x w_y \\ &= \sum_{i=1}^{m} \sum_{|x-y|\approx d} (I[k_x=0] c_{x,i} w_x) \cdot \left( \frac{1}{1+I[k_y=0]} \left( c_{y,i}^{(0)} + \frac{I[c_{y,i}=9] s_y}{m-k_y} \right) \frac{w_y}{m-k_y-1} \right) \\ &\quad - \sum_{|x-y|\approx d} (I[k_x=0] s_x w_x) \cdot \left( \frac{s_y w_y}{(1+I[k_y=0])(m-k_y)(m-k_y-1)} \right). \end{aligned}$$

The key point is that we once again have a sum of $m+1$ convolutions of the form $\sum_{|x-y|\approx d} f(x)g(y)$ and thus can compute them efficiently as before.

## ONE-REFERENCE WEIGHTED LD

When computing weighted LD using the admixed population itself as a reference with one other reference population, a polyache statistic must be used to obtain an unbiased estimator (File S1). The form of the polyache causes complications in our algebraic manipulation; however, if we restrict our attention to SNPs with no missing data, the computation can still be broken into convolutions quite naturally, albeit now requiring $O(m^2)$ FFTs rather than $O(m)$.

As in the two-reference case, the key idea is to split and factorize the weighted LD formula. We treat the terms in the polyache separately and observe that each term takes the form of a constant factor multiplied by a product of sub-terms of the form $S_{r,s}$, $p_A(x)$, or $p_A(y)$. We can use convolution to aggregate the contributions of such a term if we can factor it as a product of two pieces, one depending only on $x$ and the other only on $y$. Doing so is easy for some terms, namely those that involve only $p_A(x)$, $p_A(y)$, $S_{r,0}$, and $S_{0,s}$, as the latter two sums depend only on $x$ and $y$, respectively.

The terms involving $S_{r,s}$ with both $r$ and $s$ nonzero are more difficult to deal with but can be written as convolutions by further subdividing them. In fact, we already encountered $S_{1,1} = \sum_{i=1}^{m} c_{x,i} c_{y,i}$ in our two-reference weighted LD computation: the trick there was to split the sum

into its $m$ components, one per admixed individual, each of which could then be factored into $x$-dependent and $y$-dependent parts and aggregated via convolution.

Exactly the same decomposition works for all of the polyache terms except the one involving $S_{1,1}^2$. For this term, we write

$$S_{1,1}^2 = \sum_{i=1}^{m} c_{x,i}c_{y,i} \sum_{j=1}^{m} c_{x,j}c_{y,j} = \sum_{i=1}^{m}\sum_{j=1}^{m} c_{x,i}c_{x,j} \cdot c_{y,i}c_{y,j},$$

from which we see that splitting the squared sum into $m^2$ summands allows us to split the $x$- and $y$-dependence as desired. The upshot is that at the expense of $O(m^2)$ FFTs (and restricting our analysis to SNPs without missing data), we can also accelerate the one-reference weighted LD computation.
